PREFACE

It is hoped that this book may serve as a reference handbook for engineers practicing or investigating ore-dressing processes and also as a text-book for students of the subject. With these ends in view the text has been set in type of two sizes, the thread of description and principle being carried along in the larger type while matter of reference character, numerical data, mill performances, supplementary argument, *etc.*, are set in the smaller type.

No reference handbook in ore dressing has been published since the appearance of the third and fourth volumes of Richards' monumental work in 1909. Since that time practice in the art has been revolutionized by froth-flotation concentration of sulphide-ore slimes and by the use of ball mills and the like for fine grinding.

The subject matter of the book is arranged on the principle that the metal or mineral as used in the arts is the proper focus of interest at every mine; that the operations converging on this point are mining and treatment of the ore, refining of the treatment-plant product, and sale of the refined product; and that the unit in ore treatment is the whole mill. Pursuant to this idea the book starts off, after a short introduction, with alphabetical presentation of the metals and minerals whose ores require dressing as part of their preparation. As is, of course, natural in a book on ore treatment, dressing is the principal topic under each substance heading, but discussion of treatment is, in each case, preceded by a thorough summary of the economic elements, occurrence, uses, production, price range, *etc.* In subsequent chapters individual milling operations, such as coarse and intermediate crushing, fine grinding, screening, classification, various methods of concentration, dewatering, *etc.*, are treated separately. Sections on sampling, handling of ores and treatment products, designs of milling plants, hydrometallurgy, and on the engineering fundamentals, physics, mathematics and mechanics follow and have been contributed by associate editors who are experts in the various subjects. The sections on mathematics and mechanics were written in an endeavor so to present these engineering tools that they may be most easily picked up by an engineer who has grown rusty in their use; the presentation is, therefore, in the form of a series of rules for the solution of typical problems, with numerous examples of methods of use; the theory underlying derivation of the rules must be sought in more mathematical texts.

It follows from the statement of plan that treatment of ores of non-metallic minerals has not been segregated from treatment of metallic ores, except in so far as the alphabetical arrangement of Section 2 so serves. Such segregation is not justified on physical grounds and both metallic and non-metallic practice have suffered in the past from a wholly arbitrary separation which has resulted in ignorance among the practicioners in each field of the developments in the other.

The handbook of an art is necessarily somewhat encyclopedic in character. Notwithstanding that ore crushing, gravity concentration, dewatering, *etc.*, are merely practical applications of well understood physical phenomena, yet each operation introduces so many diverse factors, complexly interrelated and practically incapable of segregation, that it is not possible to set down quantitative rules for operation nor formulas for predicting results, and estimates of future behavior must be based principally on study of past performances. In the present book, therefore, performances of machines and processes, critically culled from the replies to an elaborate questionnaire and a large number of letters, as well as from thorough study of periodical literature, make up a large part of the text.

If exception is taken to the space allotted to such apparatus as the gravity stamp, Chilean mill, grinding pan, film sizers and to the older flotation processes, the reply is that as regards the first three the battle of extinction is only recently decided, if yet finally decisive, and that the picture of the battlefield is useful to deter others from renewing the fight; that the film sizers, imperfect as they are, remain the only tools for treating slimes not amenable to froth flotation or hydrometallurgy; and that thorough understanding of the physical principles of flotation and the no less important legal pitfalls is not to be had without acquaintance with the "prior art."

Costs as given in the text are specifically dated or the date indicated by the context. They may usually be related to present time by a multiplier representing the ratio of combined labor and commodity index figures for the published date and the present.

Textual reference to the literature is a perplexing problem in all writing, and when the number of such references runs into the thousands, as in a handbook, the difficulty is aggravated, and no solution is entirely satisfactory either to author or reader. The plan adopted herein, in all but one section, is to run the reference in the text, set off in parenthesis and abbreviated in the form adopted in legal writing where, perhaps more than in any other writing, textual references abound. The method has the distinct advantage over number reference to a bibliography that it makes immediately apparent to the reader acquainted with the literature the general source of the authority cited and eliminates the irritation involved in search for the page of bibliography, while the interruption to thought caused by the parenthetical insertion need be no greater where the parenthesis contains six or eight characters than where it contains one or two. The abbreviations used are listed on page xi.

The editor hereby makes grateful acknowledgment to his associates and publisher for their forbearance with his delay in publication, occasioned both by the magnitude of the work of writing and editing and by the stress of professional engagements; to the men and mining companies listed on the following page, for answering and permitting answer to the elaborate questionnaire that formed the foundation upon which much of the book was built; to all of the mining-machinery manufacturers who freely offered and furnished information relative to their products; and to many friends who gave uncomplainingly of their time to help.

TABLE OF CONTENTS

HANDBOOK OF ORE DRESSING

SECTION 1

INTRODUCTION

A large proportion of the inorganic and many of the organic substances that form so important a part of the structure of present-day civilization have their source in the earth's crust in such admixture, chemically or mechanically, with other substances that they are substantially useless. Rendering them into form fit for use is, very largely, a process of separation from start to finish, mining to separate them as an impure mass from the surrounding material in the earth, ore dressing to effect mechanical separation of the value-bearing constituents in this impure mass from the associated barren impurities, and finally, in most cases, chemical treatment of various kinds to break the bonds that hold the substance sought in undesirable association. Lead is typical. It occurs at scattered localities in the earth's crust, principally as a chemical compound with sulphur (galena), usually associated with other metallic sulphides and with a large preponderance of one or more of the ordinary rock-forming minerals. Its principal uses in the arts are in the form of the metal, as in pipe, tank linings, storage batteries and the like, and as a carbonate of high purity in paints. A few tons per year would satisfy the world's demand for galena as such. Chemical treatment is necessary to break the bond between lead and sulphur and collect the lead in useful form.

In the exceptional cases where galena is found in such large masses that it can be mined in a state of comparative purity, the requisite chemical treatment can be applied directly to the material as mined. But in most cases the galena occurs in small masses and grains intimately admixed with large quantities of worthless substances such as quartz or limestone, and the cost of chemical treatment to break up the galena and collect the lead is increased enormously by the presence of these diluents. Under such circumstances the material mined is first subjected to a process of mechanical separation by means of which the galena is segregated from the associated materials at a relatively small cost. The economic advantages of this treatment are made apparent in the following example.

Assume an ore consisting of galena scattered as grains and small veinlets through a body of dolomite. Assume that the mass as mined assays 5 per cent. lead, that the market price for lead is $0.07 per lb., that mining and delivery at the surface costs $3 per ton, that freight to the nearest smelter costs $5 per ton, that the smelter charge for treating material containing 5 per cent. lead is $10 per ton, that 97 per cent. of the lead in the ore is recover-

able by smelting and that the smelter pays 95 per cent. of the market price for the lead recovered. Assume further that by a process of ore dressing galena from the ore as mined can be separated from the dolomite in the form of a concentrate assaying 60 per cent. lead, that in the process 5 per cent. of the lead will be lost, that the process costs $0.75 per ton, that the freight charge on concentrate is $10 per ton, the smelter charge $2 per ton, and that 97 per cent. of the lead in the concentrate is recovered and paid for at 95 per cent. of the market price. The comparative receipts and expenditures on 100 tons of ore are shown in Table 1. In this case, which is typical, concentration changes a deficit of $11.55 per ton into a profit of $1.43 per ton.

Table 1. Comparison of profits from mining and treating a 5-per cent. lead ore, with and without concentration.

WITHOUT CONCENTRATION

Expenditures		*Receipts*	
Mining, 100 tons @ $3	$300.00	100 tons of ore produce 9700 lbs. of lead, which at 95 per cent. of 7 cents per lb. is	$645.05
Freight, 100 tons @ $5	500.00	Deficit	1154.95
Smelting, 100 tons @ $10	1000.00		
	$1800.00		$1800.00

WITH CONCENTRATION

Mining, 100 tons @ $3	$300.00	100 tons of ore produce 7.92 tons of concentrate containing 9500 lbs. of lead. This, when smelted, produces 9215 lbs. of lead which, at 95 per cent. of 7 cents per lb. is	$612.80
Concentrating, 100 tons @ $0.75	75.00		
Freight, 7.92 tons (*a*) @ $10	79.20		
Smelting, 7.92 tons @ $2	15.84		
Profit	142.76		
	$612.80		$612.80

a 100 tons of ore produce 7.92 tons of 60-per cent. concentrate under the conditions stated.

The problem of ore treatment confronts every mine manager. Mining should be looked upon as a manufacturing operation involving the production and sale of ore and ore products. If thus viewed, solution of the problem of ore treatment involves not only the technical knowledge necessary to decide upon the method or methods of treatment to which the ore is amenable, but also knowledge of the costs and possibilities of recovery by the various methods, and, more important yet, acquaintance with the possibilities of the market for the finished product. Such acquaintance must be founded on knowledge of the ultimate uses of the product, its production and price history, the ability of the market to absorb new production, the possibility and availability of substitutes, and the economic significance of differences in grade of the product marketed. The technical part of the problem is the simpler; if a relative weight can be assessed, the economic phase is the more important. The mining regions of the world are dotted with monumental failures, not the least of which are those in which every technical problem of production has been satisfactorily solved, but the problem of profitable disposal of product yet awaits solution.

Definitions. An ORE is any rock containing a valuable constituent in such amounts as to make mining and treatment of the rock to extract the valuable part a commercially profitable operation. The valuable constituent is ordinarily spoken of as VALUABLE MINERAL, often just MINERAL. The worthless part of ore is called GANGUE. In some ores the valuable mineral

is in the chemical state in which it is to be used in manufacture and the arts, for example, coal, graphite, sulphur and asbestos; in others, as for instance most ores of metals, the valuable mineral contains a worthless element in chemical combination with the metal.

The method of treatment depends upon the proportion of valuable mineral in the ore and its mode of distribution, both of which vary widely; and upon the chemical state of the valuable constituent. High-grade ores of metals are usually smelted without any preliminary treatment. For discussion of smelting see, among others, Schnabel, *Handbook of metallurgy;* Hofman, *General metallurgy, Metallurgy of lead;* Hofman and Hayward, *Metallurgy of copper;* Peters, *Principles of copper smelting, Practice of copper smelting;* Ingalls, *Metallurgy of zinc and cadmium;* Certain low-grade ores of metals are treated by methods that consist essentially in dissolving the metals from the ore by means of some solvent that does not dissolve the gangue, separating the solution from the solid residue, and separating the metal from the solution. Such processes are described in Sec. 15. All other metallic ores, if treated at all, are subjected to some mechanical process that results in separating the ore into a CONCENTRATE, containing the bulk of the valuable mineral in relatively pure form; and TAILING, consisting of gangue with but a small residue of valuable mineral. ORE DRESSING is the art of mechanical treatment of ores to produce concentrate and tailing.

Crushing is the most expensive part of ore dressing in the case of a large majority of ores. The economic minerals of gold, silver, copper, tin, lead and zinc (excluding gold- and tin-placer deposits) almost invariably occur in such a fine state of dissemination in the gangue that crushing must be carried down to a fraction of a millimeter in order to free them for separation. This work must be done in steps and there are certain machines best suited to each step in the reduction process. The crushers that first take the ore as it comes from the mine (some of them can take 6-ft. cubes) are called COARSE CRUSHERS; those that take the product of the coarse crushers and break it to a size suitable to feed to the final crushers are called INTERMEDIATE CRUSHERS. These machines take material in the range from 2½- to 6-in. and deliver it at from 1½- or 2-in. down to ½-in. size. FINE CRUSHERS or GRINDERS take the product of the intermediate crushers and deliver a product at any desired size down to about 0.05-mm. maximum.

Concentration involves subjecting the crushed product to one or more operations of various character that utilize differences in physical properties of the mineral and the gangue. The most important physical properties thus utilized are specific gravity, surface energy, color, luster and permeability. When differences in specific gravity form the basis of the concentrating process, it is called GRAVITY CONCENTRATION; the processes that utilize differences in surface energies are grouped under the name of FLOTATION; differences in color and luster are the basis for HAND PICKING; and differences in permeability are utilized in MAGNETIC CONCENTRATION.

Gravity concentration. Whenever two particles of different specific gravities are allowed to fall under the influence of gravity alone through a fluid that offers resistance to their passage, differences in the falling rate develop and these differences are greater the greater the difference in specific gravity and the greater the resistance offered by the fluid. Impractical extremes are the equal fall of a lead shot and a feather in a vacuum and the sinking of platinum and flotation of iron in a bath of mercury. Practical instances are the difference in rate of fall of gold and quartz particles of equal

size in water and the sinking of slate and flotation of coal in a semi-fluid mass composed of quartz sand mechanically maintained in suspension in water. When to this difference in falling rate is added difference in response to impulses such as the transporting effect of a substantially horizontal stream of water, the result is to spread out the different particles along the bottom of the water channel with the particles of highest specific gravity nearest the source and the lightest farthest down stream. This is the method by which gold has become concentrated in placer deposits and also that by which it is won from the accompanying gravels in sluice boxes.

The rate of fall of particles in a resistant fluid is proportional to their effective weights in the fluid. Hence large particles of a given specific gravity fall more rapidly than small particles, and of equal-sized particles of different specific gravities the denser falls more rapidly. It is apparent, then, that in a mixture of grains of different specific gravities and sizes there will be equal-falling grains of different specific gravities and that in all such equal-falling heterogenous groups the heavier will be the smaller. The process of treatment that involves separating a mixture of grains into equal-falling groups is called SORTING or CLASSIFICATION. A process that groups equal-sized grains together is called SIZING. All gravity-concentration processes that utilize as the separating medium a fluid less dense than any of the minerals in the ore consist of sorting and sizing as supplementary operations. Either may precede. If the separating medium is water, as is usual, the process is called WATER-GRAVITY CONCENTRATION, or, frequently, GRAVITY CONCENTRATION; if air is the medium, PNEUMATIC SEPARATION or AIR CLEANING. To be effective, gravity concentration requires a difference in specific gravity of at least 0.5 to 1.0, depending upon the absolute specific gravity of the lighter mineral; the smaller difference is sufficient when the lighter mineral has a density of 1.3 to 1.5 (coal), the greater is desirable when the lighter mineral is, say, quartz (sp. gr. = 2.6). The principal water-gravity concentrating machines are washers, jigs and shaking tables.

When the density of the separating medium is greater than that of the lighter mineral, sizing is unnecessary, since the buoyancy of any substance in a liquid heavier than itself is independent of the size of particle. The processes of this class are called HEAVY-FLUID PROCESSES. They have the advantage of being able to work with a smaller specific-gravity difference than water-gravity concentration or pneumatic separation. The only one of practical value at the present time is one that uses a suspension of sand in water as the separating fluid.

Flotation concentration consists in causing attachment of certain minerals, in a finely-ground state admixed with water, to gas bubbles of such size with respect to the mineral particles attached to them that the gas-mineral aggregates are buoyant in the aqueous mixture (PULP) and float away from their former associates. This differential gas attachment depends upon differences in the surface energy (connected with the luster) of the different minerals. In general, minerals of metallic luster will float while those of non-metallic luster are unaffected, but by suitable means differences in floatability of the minerals of metallic luster can be so accented that one can be floated away from another (DIFFERENTIAL FLOTATION), and, by other suitable means, certain minerals of non-metallic luster can be floated.

There are a number of distinctly different flotation processes, but only two, viz.: the AGITATION-FROTH PROCESS and the BUBBLE-COLUMN PROCESS, have been widely adopted.

Magnetic concentration utilizes differences in permeability to effect separation. Minerals such as magnetite, franklinite and pyrrhotite are relatively so highly permeable as to be readily separable from all other minerals by bringing the mixture into a weak magnetic field. Certain other minerals, notably hematite and pyrite, are rendered highly magnetic by roasting. A number of other minerals, *e.g.*, ferriferous blende, iron garnet, etc., may be separated readily from quartz, feldspar, calcite and the like by subjection to a powerful magnet. Magnetic separation may be practiced at any size, theoretically. Practically the range is below 2-in. for highly-magnetic particles and below 2-mm. for feebly-magnetic. At larger sizes the magnets must be made so heavy and powerful, in order to overcome the inertia of the particles and the necessarily large air gaps, that the machines become structurally impractical.

Hand-picking is possible whenever the valuable mineral and gangue differ distinctly in color and/or luster and when they occur as large individuals and break clean. This method of concentration is indicated when clean individuals of either gangue or mineral, 3-in. or larger in size, occur in sufficient quantity to permit one or more operators to keep busy in removing them from a traveling surface. Under such circumstances it will usually work out to be cheaper to recover valuable mineral or to discard waste in this fashion than to break further and make the separation mechanically. Hand-picking is particularly useful in coal cleaning.

Miscellaneous methods of concentration. Differences in electrical conductivity of minerals may be utilized for separation of finely-crushed, closely-sized grades. The process is called ELECTROSTATIC SEPARATION. In general the minerals of metallic luster are good conductors and those of non-metallic luster poor conductors. Blende is an exception to the general rule for metallic minerals, and this fact has been utilized (see p. 177) to effect separation from galena.

A few minerals, *e.g.*, fluorspar, DECREPITATE (disintegrate spontaneously on heating). Separation of these from others that have not this property may be made by first sizing the mixture of grains within small limits, then heating to cause decrepitation, and finally screening out the broken fragments. The process is of limited application.

Separation by oil and grease in bulk utilizes differences in the same property of minerals, *viz.*: surface energy or surface tension, that is utilized in flotation. The process is not universally applicable but two notable examples of its utility are: (a) the separation of diamonds from associated minerals, beryl, tourmaline, quartz, etc., by passing them in semi-suspension in water over a surface covered with stiff grease (GREASED TABLES), and (b) separation of coal from slate by violent agitation of the finely-ground mixture in water with a quantity of fuel oil (GRANULATION).

Recovery. Ratio of concentration. Technical success in concentration is measured by the ratio of the weight of valuable mineral in the concentrate to the weight in the original material (usually called FEED or HEADS), due regard being had also to the richness (GRADE) of the concentrate, *i.e.*, the percentage of metal contained. This ratio is known as RECOVERY or EXTRACTION. The ratio of the weight of feed to the weight of concentrate is called the RATIO OF CONCENTRATION. (For calculation and discussion of these terms see Sec. 22, Art. 14.)

The scheme of concentration (FLOW-SHEET) depends on the mineralogical character of the ore and on the size of the individual particles of the economic

mineral and of the barren or low-grade constituent. If either the economic mineral or the low-grade constituent occurs in aggregates upwards of three inches in size and in any considerable bulk at these sizes, hand-picking will probably prove desirable as the initial step in concentration, provided, as is almost invariably the case, there is sufficient difference in appearance to allow pickers to choose with speed and certainty. If the economic mineral has high unit value, it may be picked out at sizes down to 1-inch. Crushing prior to picking should be planned to do no more breaking than is necessary to sever the material that is to be picked from the balance of the ore. If, following hand-picking, the remaining ore is amenable to separation by both gravity concentration and flotation, the flow-sheet will usually show these two processes in the sequence named and the MIDDLING (partial concentrate consisting largely of unsevered grains of mineral and gangue) from treatment at coarse sizes will be re-ground to free the locked valuable mineral. If gravity concentration or magnetic separation only is applicable, it is usually applied to successively finer grades with re-grinding of the middling produced at each step. When both gravity concentration and flotation are applicable but the valuable mineral is so finely disseminated that gravity concentration at relatively coarse sizes is not possible, it becomes a serious question whether gravity concentration should be employed at all, or whether it is not best to grind immediately to flotation size and treat all the ore by this process alone. Gravity concentration is cheaper, but it ordinarily cannot reject sufficiently low-grade tailing; flotation must, therefore, be applied eventually and the saving in cost on the tonnage of concentrate removed by gravity concentration must pay for the cost of the gravity operation. This it cannot ordinarily do. The simplicity and relatively small size of the all-flotation plant would ordinarily dictate its selection even in the face of an estimated small saving in operating cost with the gravity plant ahead. If, however, the gravity plant increased the saving or raised the grade of concentrate, it would usually justify itself economically.

If the economic mineral is very finely disseminated and amenable to flotation, gravity concentration and, of course, hand-picking are out of the question entirely.

When low-intensity magnetic separation can be used, it is economically preferable to gravity concentration.

High-intensity magnetic separation, electrostatic separation and decrepitation are expensive operations, justified only when the simpler and cheaper processes fail.

The unit value of the economic mineral in an ore sets the limit to which the ultimate pursuit of that mineral in the mill can be carried profitably. It is apparent that the pursuit of gold, with a market value of \$20 per oz., can be carried further and prosecuted at greater expense per unit weight recovered than that of silver at \$0.60 per oz.; that silver can be sought more carefully and to a greater extent than copper; copper than lead, and lead than iron. It follows also that minerals of highest unit value may be profitably recovered from ores in which their dissemination is most scanty, and these ores are frequently the ones that require the greatest number of machines, *i.e.*, the greatest complexity of flow-sheet, for successful treatment.

Unit value has another phase, involving transportation and smelting charges. From the point of view of the mill operator the important unit value of his product is that in concentrate as delivered from his plant. The value of lead per pound in high-grade concentrate near a Missouri smelter

may easily be higher than that of copper in a low-grade concentrate several hundred miles from a smelter in Arizona. Similarly the net value of an ounce of gold in low-grade cyanide-process bullion, salable at the mint, may well be so much greater than that of the same ounce when contained in pyritic flotation concentrate with high freight and smelter charges yet to be paid that cyaniding will be the cheaper mill process notwithstanding probable greater costs and possible greater losses.

Mill tonnage. The size of the ore body and daily tonnage are closely related, especially if one accepts the Hoover theory of the economic life of mines (*H. C. Hoover, Principles of mining, McGraw-Hill, 1909*). Apart from this theory, a large ore body usually means a large daily tonnage and a long life, both of which elements justify large expenditures for plant and permit a multiplicity of treatment and re-treatment operations that would not be economically possible at small, short-lived mines. Consequently, all other things being equal, the flow-sheet at a large mine has more steps and is more complicated than that at a small mine.

Grade of ore. High-grade ore yields a higher recovery with a given grade of tailing than low-grade ore of the same metal, and, of course, more money per ton treated. A mill treating high-grade ore may find it economy to discharge a tailing assaying higher than the feed to a low-grade mill. In such case the flow-sheet of the high-grade mill may be and usually is simpler than that of the low-grade mill. This is particularly the case as between high-grade mills in isolated locations and low-grade mills near lines of transportation. Ordinarily, however, high-grade mills have the longer and more complex treatment schemes in proportion to the extent of treatment necessary to reduce the mill pulp to the metal content of the low-grade ore; both seek to make the same grade of tailing; both must give substantially the same final treatment, therefore, before discharge; but in the high-grade mill the process of impoverishment must be gradual, if it is to be efficient, hence in this mill a certain amount of preliminary concentration is necessary that is unnecessary in the low-grade mill.

Location of plant. (See also Sec. 23.) The principal angles from which plant location affects the flow-sheet are with respect to water, transportation and metal-buying centers. If water in excess of requirements for power and domestic use is lacking, flotation and water-gravity concentration are debarred and the ore must be transported to water (or, of course, water to the ore), or some method of dry concentration such as hand-sorting, magnetic or electrostatic separation, or air-cleaning must be employed. If ordinary transportation facilities are lacking, the flow-sheet must be one employing only machines of such size and weight (and, therefore, capacity) as can be brought in by means of the transportation available, and the process should be one that requires the minimum of outside supplies and provides a finished plant product of minimum bulk.

When transportation facilities are the poorest, economic necessity may dictate the location of a crude smelter at the milling plant. This is particularly true, if such crude smelting treatment as is possible results in considerable diminution in bulk of the plant product without too great loss of values. Ordinarily, however, milling-plant product must be transported to smelters, which are so located as to draw ores and concentrates from a considerable radius, and to be close to a source of fluxes and to a source of fuel or a direct and cheap fuel-transport line. In such case the proximity of the milling plant to the smelter is of considerable moment in determining the

character of the plant product and, therefore, of the plant flow-sheet. If the plant is near the smelter, then, all other things being equal, a lower grade of concentrate containing more moisture is permissible than when concentrate must be hauled a considerable distance. This makes for a simpler flow-sheet. In general, the greater the distance to the smelter, the smaller the bulk of concentrate must be and the greater the complexity of the plant required to produce it.

SECTION 2

METALS AND MINERALS

PROPERTIES, USES, ORES, PRODUCTION, SELLING, TREATMENT

1. Introduction

A mill is essentially a manufacturing plant for which the ore constitutes the raw material and the concentrate the finished product for market. Hence it is necessary for the designer and operator to know all that is possible about the kind and source of raw material available and the demand for and destination of the finished product. The fact that the mill owner is also usually the mine owner is not sufficient insurance as to the adequacy or kind of raw-material supply, nor is the further fact that one or more other manufacturing processes usually intervene between the mill and the ultimate consumer sufficient to excuse ignorance as to the general character of the final use of the mill product. Most mill managers are well acquainted with the demands of the immediate purchasers of their products, but these demands are sometimes based as much on the ignorance of the managers as upon the requirements of the consumers, and may be favorably modified in proportion to increase in the manager's knowledge. Omniscience is not expected nor required, but the further the operator advances from the attitude that his responsibility starts with the ore in the mill bins and ends with the concentrate in the railroad cars, the greater his value.

The elements determining the administrative problems of mill design and operation are: (*1*) The characteristics of the particular ore; (*2*) statistical facts as to world distribution and production of similar and dissimilar ores of the same metal or mineral; (*3*) uses of the finished product; (*4*) prices, current and for a sufficient time in the past to form a basis for judgment as to future trend; (*5*) mill-treatment schemes on the same and similar ores; (*6*) costs of milling similar and related ores.

Ore. The quantity and quality of ore available, either actually blocked out in the mine or positively indicated by geologic data, determine whether a mill should be built, and, if so, are also factors in the problems of capacity and type of construction. The mineralogical character of the ore determines the treatment scheme. Mill construction should never start until the existence of an amount of ore of paying quality, sufficient to repay the mill investment with interest, is established. Mill capacity is determined by potential mine capacity, first cost of mill construction, and demand for the mill product. Type of mill construction is determined by kind and size of machinery, probable life of mine, and relative costs of different materials. See also Sec. 23.

Production. Prices. Uses. District, state, national and world production are obtainable from publications of the U. S. Geol. Survey, the U. S. Department of Commerce, and various technical publications (see p. 14). Study of these together with average prices over a period of years, obtainable from the same sources, furnishes a basis for judgment as to the market for mill products, possible competition, etc. Knowledge of uses will tell something as to the probable stability of demand, wide and varied use tending toward stable, increasing demand.

The increase in the use of closed bodies for automobiles resulted in a great increase in the demand for aluminum, while the present tendency toward the use of fiber bodies threatens a decrease in this demand. Continued increase in centralization of power production together with the almost certain electrification of long stretches of railroad will result in increased demand for copper and aluminum. On the other hand, the enormous and relatively high-grade copper deposits of Central Africa are a potential damper on any great increase in copper prices for a considerable time.

In the case of certain substances, such, for instance, as zinc, graphite, molybdenite, and garnet, the grade of concentrate or its physical character, as dictated by the use, is highly important in determining the price of the mill product and even the existence of any market therefor.

2. Flow-sheets

The flow-sheet best suited to a given ore depends upon the physical character of the economic mineral and of the gangue with which it is associated, the ruling size of the particles of economic mineral, the size of the ore body, the daily tonnage, the unit value of the valuable constituent, the grade of the ore and the location of the plant with respect to markets, water, tailing-disposal space, etc. In simplest fundamentals, all concentration flow-sheets are alike in that all contain machines for severing valuable from waste mineral followed by other machines for separating the severed constituents. Further than this, however, identity ceases and cursory examination of a number of mill schemes taken at random shows a bewildering complexity. There is, nevertheless, a distinct order, which becomes apparent when the flow-sheets are analyzed in the light of the controlling factors above enumerated, and certain kinds of machines and definite sequences of these machines are found to occur with considerable regularity, coincident with similarities in fundamental conditions. This fact is not, of course, any chance or statistical agreement, but the result of recognition by flow-sheet designers of certain basic principles of design. Numerous variations in minor details are observable, which are to be attributed to local ideas or traditions, special availability of particular pieces of apparatus, or individual predilections of certain designers, but in the matter of fundamentals, arbitrary differences disappear, and the elements of the flow-sheets can be referred to a few definite principles

The important determinative characteristics of the ore are: kind of valuable mineral, kind of associated gangue minerals, relative quantities of valuable mineral and gangue, and size of valuable-mineral particles. The most important mineral properties, from the viewpoint of flow-sheet design, are specific gravity, surface energy, magnetic permeability and fracture.

Specific gravity. The important consideration is the ratio of specific gravities, each decreased by one, of the minerals to be separated. If this ratio is greater than two (the heavier mineral in the numerator) reasonable separation can be effected without too great difficulty; if the ratio is near one, it is difficult to get a high-grade concentrate, low-grade tailing is substantially impossible to obtain, and the tonnage of middling is very large. With a ratio of 2.5 it is possible to get clean concentrate, but difficult to get low-grade tailing and the tonnage of middling is large. With a ratio of 3 or more, gravity concentration is easy in all sizes down to the finest sands. No difference in specific gravity that exists between minerals is sufficient to make clean gravity separation of slime possible for the reason that with such fine particles the relation of surface to volume (and weight) is so large that the surface forces resisting settlement of the particles in fluids are sufficient to mask or completely nullify the effect of specific gravity.

Luster. If there is a marked difference in luster between valuable mineral and gangue, such as, for instance, exists between the metallic sulphides and the rock-forming silicates, flotation concentration can be used. Flotation, however, labors under a disadvantage converse to that suffered by gravity concentration in that it cannot be practiced on particles greater than 0.2-mm. diameter, and better not on particles larger than 0.15- or even 0.1-mm. size. Hence when the valuable mineral occurs in coarse aggregates and sufficient difference in specific gravity of the ore constituents exists to permit gravity concentration, flotation should ordinarily be an adjunct to gravity separation, unless the ratio of concentration is high and no gravity-concentration tailing can be made economically.

Magnetic concentration is employed under two general conditions, viz.: (*1*) when the valuable mineral is magnetite, (*2*) when the valuable and waste minerals are close together in specific gravity, not amenable to sharp separation by flotation and one is sensibly permeable to magnetic lines of force and differently permeable from the others. Magnetic concentration of highly permeable minerals can be practiced at all sizes below 2-in.; if the minerals are of low permeability, fine crushing is necessary.

Fracture. Concentration dependent upon difference in fracture of the ore constituents has limited application in treatment of metallic ores but is important in separating slate from coal.

Ratio of concentration. If the ratio of concentration (Sec. 22, Art. 15) of an ore is high, the flow-sheet should be of such character that concentration is effected at one size, in order to lessen the variety of concentrating machines and to permit use of large units with correspondingly low capital and operating charges. Under such circumstances the crushing plant may be greatly simplified, a minimum number of screens and classifiers is necessary, and expensive elevation and horizontal transport of pulp are greatly lessened. The all-flotation porphyry-copper mills are typical of this type of flow-sheet. If coarse tailing can be discarded and ultimate fine grinding is necessary, as for instance, is the case at the MESABI IRON CO. (Fig. 88) and ALASKA GASTINEAU (Fig. 75) some elaboration of flow-sheet is justified in order to save the cost of grinding low-grade material. If the ratio of concentration is low and, as usually follows, the valuable mineral occurs in coarse aggregates, a complicated flow-sheet with a multiplicity of screens, classifiers and concentrating machines of varied types may be justified on the grounds that coarse concentrate is usually of higher grade than fine, is more cheaply and efficiently smelted, that an appreciable tonnage is diverted from the grinding machines and over-all recovery is bettered. The basis of the final statement is that a particle of, say, a size that would go into coarse-jig concentrate will, if broken, form some slime particles, and since the recovery of slime particles is never perfect, a part of this broken particle is discarded as tailing, with resultant lowering of recovery. If slime recovery is efficient, this argument has but

little weight and a coarse concentrator must justify its inclusion on the first three grounds mentioned. Flotation is so efficient, and the size that can be handled on shaking tables has increased so greatly in recent years, that jigs have been eliminated from many mills. Such elimination, in addition to simplification of flow-sheet, permits removal of several screens and saves water, labor, considerable maintenance, floor space, head room and may even lessen the total power consumption. Tables are almost always used with ores of low concentrating ratio, if gravity concentration is feasible, even when flotation is most efficient. The flotation machines can make a lower-grade tailing with low-grade than with high-grade feed, some burden is taken off the grinding machines, and the cost of dewatering granular table concentrate is much less than that for flotation concentrate.

Rich ores both require and can stand the cost of more elaborate treatment than poor ores; large ore bodies justify not only larger but more elaborate mills than small; and valuable substances such as gold, silver and tin can, economically, be pursued further, *i.e.*, according to a more elaborate flow-sheet, than lead, zinc or iron. When freight rates are high or smelter penalties for impurities great, extensive (and expensive) treatment designed to raise the grade of concentrate is justified, or high-grade concentrate may be made at the expense of a low recovery, while with low concentrate-treatment and transportation charges, the flow-sheet should be designed for high recovery with less attention to the grade of the final product.

Tonnage is an important factor in flow-sheet design. If tonnage is small, say less than 500 tons per 24 hr., the simplest type of flow-sheet, only, should be considered, even when a low ratio of concentration might indicate an elaborate mill. Multiplication of machines under such circumstances makes for small and relatively inefficient units and increases capital and operating costs out of proportion to the savings otherwise effected. When tonnage is large, a mill is designed in independent sections, the flow-sheets of which are substantially the same, the tonnage going to each section being determined usually as that of the largest-tonnage unit or convenient group of units. The advantages of such design are: (*1*) that it permits one or more sections to be shut down for repairs, curtailment or the like without affecting the efficient operation of the balance of the plant, and (*2*) that responsibility for efficient operation of machines can be localized and a competitive spirit engendered between the workmen. Capacity is readily increased by adding sections without materially affecting current operations.

Water supply. Scarcity of water may dictate dry treatment when otherwise wet treatment was indicated, as *e.g.*, at some coal-cleaning plants; it may make it necessary to plan for a smaller daily tonnage than otherwise; and it usually requires inclusion in the flow-sheet of a more or less elaborate water-reclamation system.

Essential elements of a flow-sheet are crushing, grinding, concentrating, concentrate handling, sampling and weighing, storage and transportation of pulp. The first three of these elements, in any flow-sheet, are primarily dependent upon the ore as delivered from the mine; concentrate handling depends upon the method of concentration and upon the after-treatment of the concentrate; sampling and weighing are matters of efficient mill control; and storage and pulp transport are solely mechanical features, substantially independent of the character of the ore and of the process of concentration, but of supreme importance from the standpoint of smooth and efficient operation.

General bibliography for metals and minerals

1. Mineral resources of the U. S., Annual, U. S. Geol. Survey.

2. Mineral Industry, Annual, McGraw-Hill Book Co., N. Y.

3. The marketing of metals and minerals, J. E. Spurr and F. E. Wormser, McGraw-Hill Book Co., N. Y., 1925.

4. Non-metallic minerals, R. B. Ladoo, McGraw-Hill Book Co., N. Y. 1925.

5. Engineering and Mining Journal, annual review numbers and weekly price lists.

3. Aluminum, Al.

Properties. Metal; bluish-white, lustrous, highly malleable and ductile; TENSILE STRENGTH, pure cast aluminum, 18,000 lb. per sq. in.; rolled sheet and wire up to 40,000 lb. per sq. in.; ELASTIC LIMIT from 8500 lb. per sq. in. for castings to 33,000 lb. per sq. in. for fine wire. (See also Table 1.) AT. WGT., 27.0. Practically unchanged in air due to rapid formation of a thin, firmly-adhering layer of aluminum oxide. Substantially without action on water at any temperature. Reacts with strong bases to form aluminates and with hydrochloric and sulphuric acids to form corresponding salts. With nitric acid oxidation takes place and the film of oxide protects the metal from further action. Organic acids attack pure aluminum only slightly. Aluminum ion is tri-valent. Aluminum alloys readily with copper, zinc, tin, nickel, magnesium and tungsten.

Uses. Aluminum metal is used for structural shapes and castings where lightness is essential, principally in airplane and automobile construction; electrical transmission, cooking utensils, scientific instruments, alloys, lithographic work as a substitute for stone or zinc, de-oxidation of steel in casting, thermit welding, explosives, etc. Bauxite, beside its use as a source of metallic aluminum, is used for manufacturing aluminum chemicals, for making abrasives such as alundum, and for refractories.

Ores. Aluminum is widely distributed as a large constituent of many different minerals, but extraction is commercially possible only from bauxite and cryolite. BAUXITE occurs as pisolites and clay-like masses in pockets or lenses in residual clays. CRYOLITE occurs as lenses or veins in metamorphic rocks. At present bauxite ores form practically the only commercial source of aluminum. Principal economic occurrences of bauxite in the United States are in Georgia, Alabama, Tennessee and Arkansas. Principal foreign localities are France, Italy, Dalmatia and British Guiana. Analyses range from 50 to 60 per cent. Al_2O_3, 2 to 20 per cent. SiO_2, 1 to 25 per cent. Fe_2O_3 and 1 to 3 per cent. TiO_2.

Production statistics are given in Tables 2, 3 and 4.

Table 2. World's production of aluminum (thousands of metric tons). (*After Mineral Industry.*)

a Estimate *(119 J 95)*.

Selling. *(118 J 851.)* Prices for 99-per cent. aluminum metal since 1913 are given in Table 5; 98-per cent. metal is quoted about one cent less per pound. Metal prices are not necessarily an index to prices for mine products for the reason that extraction of metal from bauxite in the United States is a virtual monopoly, protected by a high tariff, and intrenched against competition by the extreme costliness of plant. Average prices for bauxite at the mines have ranged, since 1913, from \$4.75 per long ton in that year to \$6.04 in 1923, with a high of \$6.38 in 1921. Open-market quotations on domestic bauxite in 1924 ranged from \$5.50 to \$8.75 per long ton, depending on purity, and imported at \$5 to \$7.50 per ton at eastern ports. These prices also must be used with caution, since the Aluminum Co. of America, which is the principal user, is also the largest mine owner. Requirements as to composition of bauxite vary according to the use. Alumina content should be 50 to 52 per cent. Al_2O_3 as a minimum. Low silica (less than 7 per cent.) is required

for aluminum manufacture and Fe_2O_3 should not exceed 6.5 per cent.; low iron and titanium (2.5 to 3 per cent. maximum) are preferred in the manufacture of aluminum chemicals, but silica may be high (15 to 20 per cent.); for manufacture of aluminum abrasives silica and ferric oxide should be less than 5 per cent. each and titanium oxide less than 4 per cent. For refractories, iron and titanium must be low but silica may be high.

b Approximate.

Treatment. Practically all the bauxite now mined is of sufficiently high grade so that no mechanical separation from associated minerals is necessary. In the past loose mixtures of bauxite and clay have been concentrated in log washers, but the low-grade deposits cannot compete at present. Treatment at one large plant consists of coarse breaking, the hard rock in gyratories, the soft in Fairmount crushers; followed by drying in coal-burning rotary kilns, about 7 × 50 ft., at a temperature near 1100° F.; thence to a cooling conveyor and shipping bins. Residual mechanically-held moisture is from 0.5 to 1 per cent. The bauxite also contains from 15 to 33 per cent. combined water, which, if the ore is to be used for abrasives and refractories, is driven out by heating at about 2000° F. in 6 × 60-ft. kilns, leaving a total moisture content of about 0.5 per cent. Simpler methods of the same general character are followed at smaller plants. Some mines ship the ore as mined, but this is extremely uneconomical, if the haul is long, on account of the high water content.

Aluminum is obtained from bauxite by electrolysis in a fused bath of cryolite. The best grades of metal contain 99.5 to 99.9 per cent. Al; poorer grades, 94 to 96 per cent. Al. Impurities are Fe and Si. Grade of finished metal is largely dependent on purity of bauxite.

4. Antimony, Sb

Properties. Metal, silver-white, lustrous, hard and brittle. (See also Table 1.) Impurities dull the luster and make the metal less crystalline. AT. WGT., 121.8. Unacted upon by dry air at ordinary temperatures but burns in air, if sufficiently heated, forming dense fumes of white oxide. Slightly tarnished by moist air at ordinary temperatures. Decomposes water at red heat. Oxidized by nitric acid. Dissolves in aqua regia and hot concentrated sulphuric acid. Antimony ion is tri-valent and quinque-valent, acid, and both base- and acid-forming. Antimony alloys freely with other metals.

Uses. Antimony metal has little or no use as such. The principal use is in alloys such as Babbitt metal, Britannia metal, shrapnel lead, hard lead for plumbing and similar purposes, type metal, white metal, pewter, storage-battery plates, solder and various other soft metals used in making foil, metal tubes, etc. Antimony persulphide is used in vulcanizing rubber, the trisulphide for safety matches, and the powdered metal, trioxide and trisulphide are all used for pigments.

Ores. The economic minerals are stibnite, senarmontite, valentinite and cervantite. Ores are found in most countries, but the Chinese deposits around Changsha yield 80 to 90 per cent. of the world supply. These

deposits consist of stibnite of remarkable purity occurring as pockets and bunches in dolomitic limestone.

Production. See Table 6.

Table 6. World's production of antimony (metric tons). (*USGS and MI*)

a No antimony metal produced from ores but considerable as a constituent of hard lead from lead ores containing antimony. *b* Data incomplete; probably larger.

Selling. Market demand is for antimony metal or REGULUS containing at least 99 per cent. antimony, as little arsenic as possible and of uniform quality. Because of the fact that the trade has become accustomed to a radiating crystalline structure, caused by doing the final refining beneath a layer of flux, it is practically necessary to market the metal in this "star" condition, although equal purity may be obtained in a different physical state. Average New York price since 1913 is shown in Table 7. Supply is far in excess of demand under normal conditions.

Treatment. (*8 AIM 196*). Only high-grade ore is mined, most of which is sufficiently concentrated by crude hand picking. If further concentration is necessary, it may be readily effected by liquation at a low temperature. Both methods are extremely wasteful (liquation losses may run as high as 30 per cent. antimony) but only high-grade material can be shipped from isolated districts to the smelters and even in the period of high costs during the war it was considered more economical to bear the losses attendant upon these crude methods than to practice more refined (and hence more costly) concentration methods. Three methods are used to recover metal from concentrate. (*1*) Roast to the volatile trioxide or non-volatile tetroxide and reduce to metal in furnaces or crucibles under a flux of sodium chloride, soda ash or sodium sulphide. (*2*) Fuse the sulphide in crucibles with metallic iron and suitable fluxes, producing iron sulphide and crude metallic antimony, and refine the latter by fusion in a reverberatory furnace or crucible with potash, antimony sulphide and other fluxes. (*3*) Electrolysis of a solution of stibnite in sodium sulphide. This produces substantially pure metallic antimony in powdered form and this must be melted down under fluxes to

produce the "Star-brand" ingots. Antimonial or HARD LEAD containing 10 to 20 per cent. Sb is obtained as a by-product in smelting and refining antimonial-lead concentrate.

5. Arsenic, As

Properties. Metal; steel-gray, lustrous and crystalline, or black, dull and amorphous; brittle. (See also Table 1.) AT. WGT., 75.0. Unaltered in dry air, becomes tarnished in moist air, burns at 180° C. in air or oxygen with bluish flame forming arsenic trioxide. Not attacked by water. Does not dissolve in hydrochloric or sulphuric acid or bases, but is slowly oxidized and dissolved by nitric acid. Combines directly with most elements. Arsenic is tri- and quinque-valent and both base- and acid-forming. It alloys with many metals, almost invariably forming a brittle alloy.

Uses. The principal uses are for insecticides such as Paris green and lead arsenate for plant sprays and calcium arsenate for boll-weevil extermination. Sodium arsenite is used in considerable quantities on railroads and highways for a liquid weed killer. The white oxide is used in glass making to mask the coloring effect of metallic oxides and impart brilliancy. It is also used in making sheep and cattle dips. The red and yellow sulphides are used for pigments in paints, calico printing, dyeing and tanning. Small amounts of the element are used for certain alloys, principally lead shot.

Ores. Arsenic occurs as a constituent of 30 or more minerals (Hess, *MR, 1914 p. 957*) but the principal sources are arsenopyrite, arsenides and sulpharsenides associated with ores of lead, copper and the precious metals, the arsenic being a by-product. Arsenopyrite is mined for the arsenic content in a few places. Realgar and orpiment occur as vein minerals associated with barite, stibnite, quartz, pyrite, and precious metals, but there is little or no mining of such deposits for arsenic content.

Production. See Table 8.

Table 8. World's production of white arsenic (in metric tons). (*MR and MI*)

Table 9. Price range of arsenic trioxide. (*MR, MI, J*)

Year	Cents per lb.
1916	3.5 to 8
1917	8.2 to 15
1918	9
1919	8 to 10.5
1920	9.1 to 14.5
1921	7 to 12
1922	6.9 to 14.5
1923	9 to 15.5
1924	6 to 13.5

Selling. The commercial form is the trioxide, 99 per cent. or better purity, white and finely powdered. A small amount of lower-grade off-color material is sold. The price has increased in recent years due to the growing use of calcium arsenate in controlling boll-weevil damage to cotton. Production facilities have increased greatly as a result until now they are probably in excess of normal demand. Range of 5-yearly average prices of trioxide

from 1901 to 1915 was 2.74 to 3.15 cents per lb. Range since 1915 is given in Table 9.

Treatment. Arsenical fumes and dust from bag houses and Cottrell precipitators in lead and copper smelters are calcined or roasted in reverberatory or special furnaces and the fume condensed in an ordinary flue system. This fume is known as black dust and contains about 90 per cent. As_2O_3. It is refined in a coke-fired furnace connected to a special flue system in which the refined (+ 99 per cent.) As_2O_3 collects.

6. Asbestos

Properties. Asbestos is a name describing a fibrous form of several different minerals rather than the name of one definite mineral. The usual minerals that occur in fibrous form and are classed as asbestos are chrysotile, $3\ MgO \cdot 2\ SiO_2 \cdot 2\ H_2O$, a variety of serpentine; tremolite, $CaO \cdot 3\ MgO \cdot 4\ SiO_2$; actinolite, $CaO \cdot 3(Mg,Fe)O \cdot 4\ SiO_2$; crocidolite, $NaFe(SiO_3)_2 \cdot FeSiO_3$; and anthophyllite $(MgFe)O \cdot SiO_2$, all varieties of amphibole. Another variety of amphibole recently discovered in South Africa and there mined is called amosite. Its ANALYSIS, compared with average analyses of chrysotile, crocidolite and anthophyllite is given in Table 10. SP. GR. of chrysotile is 2.2 to 2.65 and of the amphibole

Table 10. Analyses of asbestos minerals. (*After Ru Keyser, 113 J 619*)

varieties, 2.9 to 3.2. LENGTH OF FIBER ranges ordinarily from ⅛ in. or less to 1½ or 2 in.; exceptionally fiber as long as 24 in. has been found. Amosite fiber is longer than the average. Fiber strength and flexibility, fineness of fiber, and resistance to heat and acids are important elements in judging the value of asbestos. Chrysotile has high flexibility and medium strength and resistance to heat and acids. Crocidolite has higher tensile strength than chrysotile but less resistance to heat. Anthophyllite has low strength and flexibility but high resistance to heat and acids. Amosite has less strength and flexibility than chrysotile, but is similar in its resistance to heat and acids.

Uses. Asbestos is used widely for purposes involving resistance to acids and to relatively low degrees of heat. Long-fiber material is consumed principally in making automobile brake bands; other uses are for fireproof curtains and articles of clothing, packings and gaskets, thread and wicking, electrical insulation, chemical-laboratory apparatus and supplies, etc. Short-fiber grades are used in making shingles and asphaltic roofings, pipe coverings, paper and millboard, and asbestos cements that are used for heat insulation on hot and cold pipes, stoves and furnaces, fireproof safes and the like.

Ores. Asbestos fiber occurs in three forms in the country rock, known respectively as cross-fiber veins, slip-fiber veins and mass fiber. In cross-fiber veins the filaments are oriented at right angles to the vein walls. Filaments in slip-fiber veins are not so regularly oriented as the cross-fiber, but such orientation as exists is generally parallel to the vein walls. Mass fiber occurs in unoriented masses disseminated through the country rock. Cross-

fiber is much the best from the point of view of fiber length. The veins of asbestos occur in association with serpentine in limestone and dolomite and in altered peridotites.

Production. The United States is the principal consumer of asbestos but a negligible producer. Imports of unmanufactured asbestos have increased from 64,000 long tons in 1914 to nearly 190,000 in 1923, while production since 1918 has ranged between 67 tons minimum in 1922 and 1650 tons maximum in 1920. Canada is the principal world producer, with a record volume of 233,000 short tons in 1923. In the same year Rhodesia produced about 20,000 tons; Union of South Africa, 8400 tons; and seattered small amounts were mined in Australia, Corsica, Cyprus, Madagascar, New Zealand and Russia. The latter country exported about 11,000 tons annually before the revolution.

Selling. Fiber is graded differently by different producers, but in general, the grading corresponds approximately to that shown in Table 11 (*114 J 277*). The average price of all grades sold in Canada ranged between $10 and $20 per ton from 1912 until 1916, when it began to climb, reaching $80 in 1919. The peak was reached in 1921. In that year No. 1 crude sold at $3000 per ton compared to $350 in 1913.

Table 11. Grades and prices of Canadian asbestos.

Trade name	Fiber length	Price (Oct., 1925), dollars per short ton
No. 1 crude	+ ¾-in.	400–450

Floats or shorts (*b*)	....	8–12
Sand	....	6–8

a Mill fiber is tested in a standard machine consisting of three nested shaking screens, respectively 2-mesh 11-gage, 4-mesh 17-gage and 10-mesh 20-gage, and a bottom box. Screen frames and box are of wood, rectangular, 16 × 26 in. × 5 in. deep. A 1-lb. sample is placed on the top (coarsest) screen and the nest is mechanically shaken for two minutes at 300 r.p.m. Oversizes and final undersize are weighed in ounces and the weights in order from coarse to fine are recorded, as in the table. Thus 2–8–4–2 means 2 oz. on 2-mesh, 8 oz. on 4-mesh, 4 oz. on 10-mesh and 2 oz. through 10-mesh. *b* This is material finer than any of the preceding and containing much dust and dirt.

Treatment of asbestos-bearing rock involves many problems not present in ordinary concentrating practice. In the first place, as may be seen by reference to Table 11, the value of long fiber is much greater than the value of the same material in shorter lengths, hence every endeavor is made to prevent fiber breakage. The valuable and gangue minerals are not of sufficiently different specific gravities to make them separable by gravity-concentration processes without close sizing, and the nature of the asbestos aggregates prevents such preparation. As a result of these facts a system of treatment has evolved that consists of coarse crushing, drying, screening, separating asbestos from screen oversize by suction, and subsequently separating rock dust from the sucked-up product by screening. This final screening is arranged to divide the asbestos into market grades (see Table 11). Crushing

is carried down as far as possible in jaw and gyratory crushers because these machines do the least injury to fiber. Rolls are unsuitable as they mat together the fiber and associated clayey material. In the fine-crushing section free fiber is separated ahead of each crusher. Treatment differs somewhat according to whether the ore is of the cross-fiber variety or slip or mass-fiber rock. Ru Keyser (*113 J 672*) gives the generalized flow-sheets shown in Figs. 1 and 3 to illustrate typical Canadian practice.

Recent experiment has indicated a good possibility that coarse fiber may be separated by jigging and fine fiber by tabling, the fiber discharging, irrespective of specific gravity, from the tailing outlets of the respective machines. The principle involved is the same as that which acts in the present screening practice, *i.e.*, the fiber works to the top (more properly, the granular material works to the bottom) of a mass of rock and asbestos when it is sufficiently agitated to give the particles partial relative mobility, due to the fact that the elongated and somewhat fluffy asbestos bridges over the interstices in the mass while the granular rock particles enter these interstices and work toward the bottom. If further experiment proves wet separation effective, milling plants should be much improved. Dust with its evil mechanical and physiological effects will be largely eliminated, drying will be confined to a small proportion of the mill tonnage, and it should be possible to substitute cylinder mills for the relatively inefficient jumbos, cyclones, and the like.

Typical slip-fiber asbestos mill. Fig. 1. (*113 J 672*).

Location: East Broughton, Que., Canada.

Ore: Chrysotile in serpentine associated with basic igneous rocks. Slip-fiber occurrence.

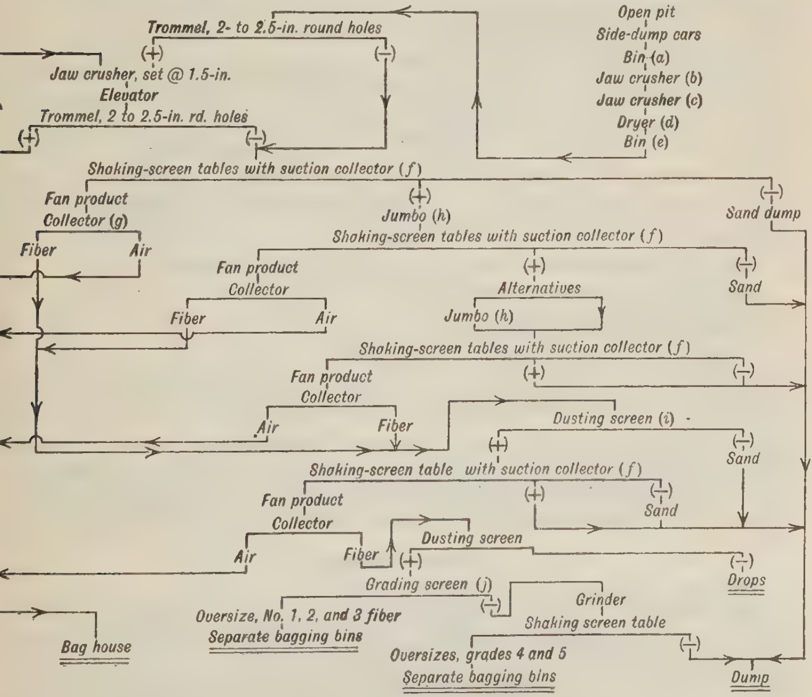

FIG. 1.—Typical slip-fiber asbestos mill.

a, Usually not more than 1-day capacity. Great difficulty is encountered in moving material through this bin in winter on account of freezing. At the JOHNS-MANVILLE

plant the cars dump directly into the primary crusher (see note *b*). *b*, At KING mine, 2 @ 32 × 72-in. At JOHNS-MANVILLE 1 @ 60 × 84-in. set 10 in. Capacity 3000 tons per 8 hr. Nip angle 18° on account of slippery nature of rock. *c*, At KING mine, 3 @ 15 × 20-in. set 2.5-in. Usual practice is 2 or 3 stages of jaw or gyratory crushing from run-of-mine to 2- or 2.5-in. *d*, In all but one mill rotary cylindrical dryers of either the direct- or indirect-heat type are used, 4½ to 6 ft. diam. × 30 to 50 ft. long. One mill uses a tower dryer 40 ft. high. Extent of drying is important. Too little makes subsequent separation difficult, too much causes partial dehydration and injury of fiber. *e*, Bulk of storage capacity is usually placed at this point. At two of the mines dry-rock bin capacity is 25,000 tons. With such storage it is possible to keep the mill running and shut down the quarry and coarse crushers in the worst weather. *f*, These average about 6 ft. wide × 20 ft. long, frequently stepped into 2 or 3 decks, and are covered with screen having about 1/16-in. openings. Speed @ 300 r.p.m. The suction pipe of a rotary fan, suitably shaped (see Fig. 2), is suspended above the screen near the end of each deck. *g*, Usual conical type. *h*, Or other type of disintegrator, *e.g.*, cyclone, swing-hammer pulverizer or the like. (See Sec. 4, Art. 21.) *i*, Usually a rotary or hexagonal trommel with about 1/16-in. screen. Vibrating screens are now coming into use. *j*, Screen apertures correspond to those on asbestos-testing sieves, *viz.*: 2-mesh, 4-mesh and 10-mesh. (See note *a*, Table 11.)

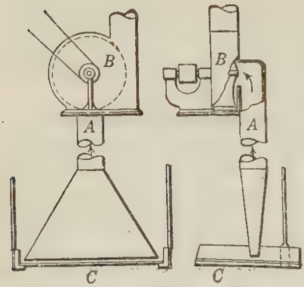

FIG. 2.—Suction fan for asbestos table.

Capacity: 800 to 1000 tons per 24 hr.

Assays: Feed and products are not capable of ordinary chemical assay, and an actual run is necessary in order to determine the amount of recoverable fiber present.

Recovery is stated as the percentage of total rock mined (or milled) that is shipped as asbestos. This method, of course, gives no measure of the efficiency of the concentrating process. Average per cent. of fiber extraction at the Quebec mines has been between 6 and 7.

Cost: Ru Keyser gives the following as typical of an 800-ton plant in 1919: Total expense per ton mined and milled, $1.65; value of ore per ton milled, $2.60; recovery of fiber, 4.81 per cent.; average selling price of fiber, $60 per ton; average operating cost of producing fiber, $38 per ton.

Typical cross-fiber asbestos treatment (*113 J 673*). Fig. 3.

Location: Thetford district, Que., Canada.

Ore: Chrysotile in serpentine.

Capacity: 800 to 1000 tons per 24 hr.

Assays: See corresponding note on slip-fiber mills.

Recovery: See corresponding note on slip-fiber mills. Recovery of No. 1 crude ranged downward from 0.1 per cent. in 1910 to 0.033 per cent. in 1920. Recovery of No. 2 crude has increased in the same time but total recovery of crude is not, in general, over 0.75 per cent.

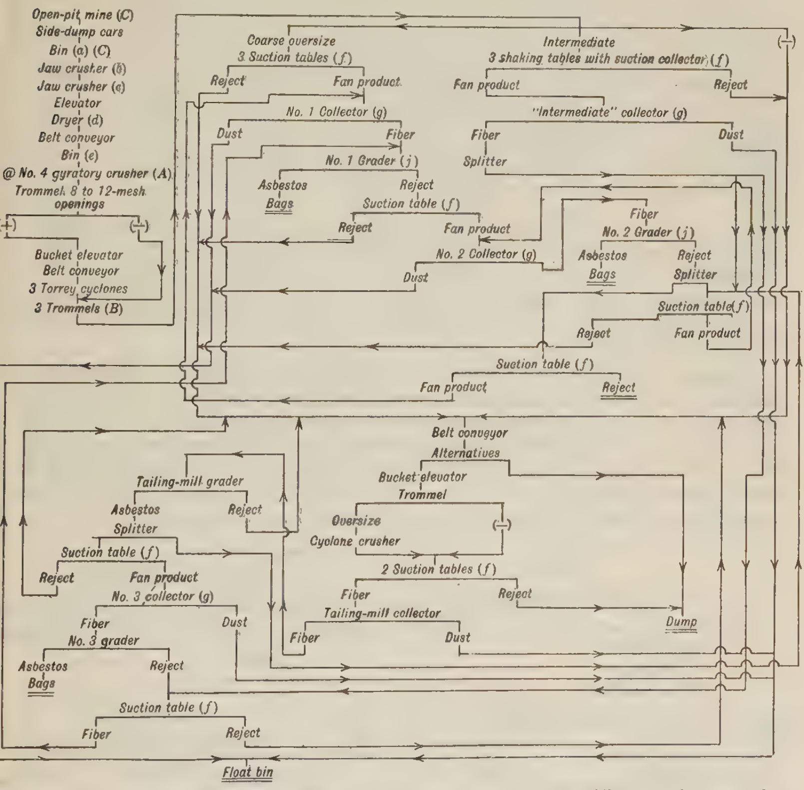
Cost: Ru Keyser gives the following as typical of 1921 operation. Value of fiber per ton of rock mined, $2.51; value of crude and fiber per ton mined, $3.43; total expense per ton mined and milled, $1.48; average value of fiber, $329.75 per ton; average total expense per ton of fiber, $147.25. Cost of milling, bagging, loading and of mine (and mill) overhead is about 45 to 50 cents per ton milled. About two-thirds of the rock mined goes to the mill.

7. Barite, $BaSO_4$

Properties. Crystalline, concretionary or earthy. COLOR: white when pure; impure varieties are red, yellow, gray, blue or brown. LUSTER: vitreous to resinous or pearly. SP. GR., 4.3 to 4.6. HARDNESS, 2.5 to 3.5. Insoluble in water and acids. Decrepitates and loses SO_3 on heating; fuses at high temperatures.

Uses. The principal uses are in the manufacture of white pigments and in making barium chemicals for various uses. Ground barite itself is used as a pigment, as a filler for paper, cardboard, rubber, linoleum, artificial ivory and in many other places where a heavy, inert filler is desired. LITHOPONE, which is the principal barium pigment, is composed of about 70 per cent. precipitated barium sulphate and 30 per cent of a mixture of 1 to 3 per cent. zinc oxide and the balance zinc sulphide (see *Ladoo, Non-metallic minerals,*

p. 78, for outline of method of manufacture). Various barium chemicals, including the precipitated sulphate, the nitrate, chloride, sulphide, oxides and hydroxide, chlorate and chromate are used in the manufacture of white-rubber goods, asbestos cement, ceramics, enamels, boiler compounds, insecticides, fertilizers, hydrogen peroxide, special glass, etc. (For detailed extensive list of uses see *Bul. 35, Geol. Surv. of Ga.*) Forty to 50 per cent. of the barite produced goes into lithopone manufacture, 25 per cent. into manufacture of barium chemicals; the balance is ground to fine powder and used thus.



a, b, c, etc., For lower-case reference numbers read notes to Fig. 1. *A*, Probably better practice than the jaw crusher in corresponding position in slip-fiber flow-sheet. *B*, Two screens on each, finer 8- to 12-mesh. *C*, Ore is usually cobbed both at the mine and ahead of or following the primary breaker for the recovery of "crude" fiber.

Fig. 3.—Typical cross-fiber asbestos mill.

Ores. Barite ($BaSO_4$) and witherite ($BaCO_3$) are the principal economic minerals. United States deposits are barite in the form of particles ranging from small grains to masses containing 1 or 2 cu. ft. together with grains and masses of chert in residual, unconsolidated clays and soils. The barite particles may be either hard and crystalline or soft and granular. The latter is preferred, as it is easier to grind. Some foreign barite deposits are of vein type.

Production. World production of barite minerals for the years 1919 to 1923 compared to that for 1913 is shown in Table 12. The principal producing regions in the United States are in Missouri and Georgia. These two states accounted for 80 per cent. of the total domestic production in 1923, with Tennessee third with 11 per cent.

a Data not available. *b* Complete data not available. *c* Estimated. *d* Algeria, Canada, Rhodesia, Russia.

Selling. (*114 J 109*) Crude barite should contain upward of 90 per cent. $BaSO_4$. The usual washed product contains 95 to 98 per cent. The average price of crude per long ton, f.o.b. mines ranged from $5.66 in 1917 through a peak of $9.08 in 1920 to $7.77 in 1923. *Eng. and Min. Jour.* quotation, Oct. 3, 1925, was $7 @ $8.50 per long ton of crude, f.o.b. mines; ground off-color, $14 @ $17 per short ton, f.o.b. So. Carolina mills; water-ground, bleached and floated, $23 to $24 f.o.b. works, St. Louis.

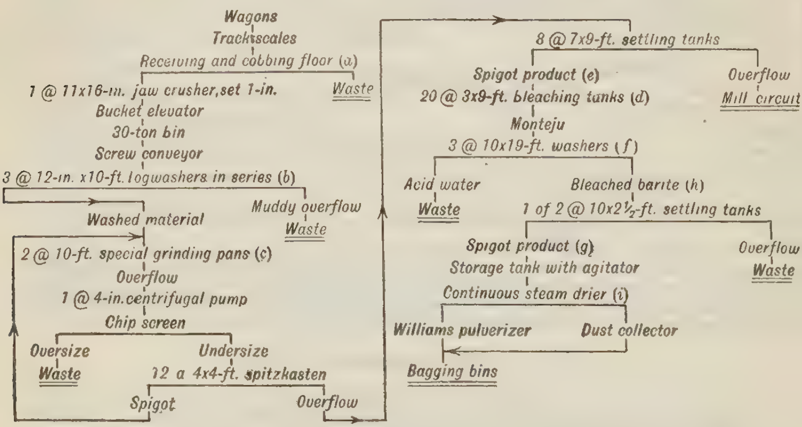

Fig. 4.—Point Milling and Manufacturing Co.

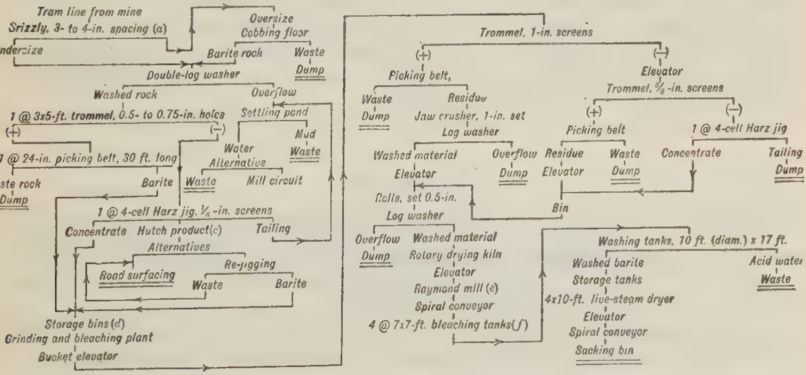
a, Pneumatic chisel used for cleaning lumps. *b*, Logs made of screw-conveyor spiral on 20° slope. Conveyor spiral has V-notches, 1.5 in. deep at 4-in. intervals. Spiral submerged for two-thirds of its length. Unsubmerged end is sprayed with 25 @ ⅛-in. jets under 45-lb. pressure. Each machine requires 40 gal. water per min. Capacity of the three is 120 tons washed sand per 24 hr. *c*, Steel sides 3 ft. high. Bottom paved with cut

blocks of local granite. 20 r.p.m. Drag stones roughly triangular, 36 in. on a side and 18 in. thick when new, arranged so that the leading angle can be changed as necessary to produce even wear. Life of stones about 3 yr.; life of bottom about 18 mo. to 2 yr. Should be about 8 in. of barite on the bottom for the best operation. Capacity of each mill is 12 to 18 tons per 24 hr. and each requires about 15 hp. ***d,*** Tanks are made of vitreous tile surrounded by hard lead which is in turn surrounded by oak staves and iron hoops. Charge is 2 tons of barite containing 25 per cent. water and a minimum of 240 lb. @ 66 per cent. H_2SO_4. About 45 min. is required to heat the mixture nearly to boiling with steam and 6 to 7 hr. minimum to bleach. If bleaching is not complete in 12 hr. more acid is added. ***e,*** About 25 per cent. moisture. ***f,*** Arranged for washing by continuous decantation. ***g,*** 15 per cent. moisture. ***h,*** Acid must not be completely removed or product turns yellow. Leave just enough so that the iron sulphate also present gives a slight blue color with potassium ferrocyanide. ***i,*** 3 × 8-ft. wrought-iron pipe, driven 1.5 r.p.m. and heated inside with live steam. Wet material is fed onto the outside at the top by means of a shaking feeder 8 ft. wide (200 r.p.m.), which in turn is fed in fine streams 4 in. apart by pin valves. Thus the feed comes onto the dryer in drops and adheres. Dried material is scraped off on the rising side near the feed point. The cylinder is mounted over a hopper lined with pipes carrying exhaust water from the cylinder. Spills are caught and dried therein.

Treatment varies with the character of the ore and the scale of mining. At the usual small-scale Missouri plant the ore is roughly picked, dried on floors and then "rattled" in a box screen with 1-in. holes. This treatment removes clay and sand as undersize which may be hand-jigged or rejected. Oversize is hand picked. Larger plants wash the crude ore in log-washers, with or without preliminary crushing, screen the washer sand, hand-pick the oversize and jig undersize. Fig. 4 shows the flow-sheet of a typical Missouri washer and Fig. 5 the rather more complicated scheme of a Georgia washer. Cost of the Georgia washing plant, down to and including the washed-ore storage bin was \$5000 to \$6000 in 1919.

Point Milling and Manufacturing Co. (*40 A 711*). Fig. 4.
Location: Mineral Point, Mo.
Ore: Barite and chert in residual clay.
Capacity: 35 tons cleaned barite per 24 hr., 500 to 600 tons feed.
Ratio of concentration: 15 or 20 to 1.
Product is said to all pass a 300-mesh sieve.

Thompson-Weinman Co. (*Bul. 36, Geol. Survey of Ga.*). Fig. 5.
Location: Cartersville, Ga.
Ore: Barite and chert in loose clay and soil.
Capacity: 60 tons white barite per day.



a, 7 steel rails, 12 ft. long. ***d,*** Better than9 2 per cent. $BaSO_4$. ***e,*** Product, 200-mesh. ***f,*** Lead- and brick-lined.

Fig. 5.—Thompson-Weinman Co., barite plant.

8. Bismuth, Bi

Properties. Metal; reddish-white, lustrous, crystalline; soft, brittle. Bismuth is the most highly diamagnetic substance known. (See also Table 1.) AT. WGT., 209.0. Remains unchanged in air and water at ordinary temperatures. At red heat burns in air and slowly decomposes steam. Not affected by dilute acids nor by concentrated hydrochloric acid. Concentrated sulphuric acid and concentrated nitric acid dissolve it, with the formation of the corresponding salts. Bismuth ion is tri-valent and quinque-valent and, so far as known, base-forming only. Bismuth alloys readily with other metals.

Uses. Metallic bismuth is used almost exclusively in making low melting-point alloys with tin, lead, cadmium, and mercury. Bismuth compounds are used extensively in medicine. They find some use also in porcelain and glass making, and in pigments.

Ores. The principal minerals are the native metal and bismuthinite, bismite and bismutite. The principal deposit of the world is in Bolivia, where bismuthinite occurs in veins associated with tin and silver minerals. Native bismuth and bismuthinite commonly occur in veins associated with pyrrhotite, pyrite, molybdenite, wolframite and precious metals. Native bismuth is sometimes found in sluice boxes. Carbonates and oxides of bismuth occur as residual deposits from leaching of rocks containing primary bismuth minerals. In such occurrences the bismuth is often associated with clays.

Production. Domestic production amounts to 100 to 150 tons of metal per year and this satisfies the domestic demand. The principal foreign producers are Bolivia and Australia, the product of each country ranging between 100 and 250 tons of metal per year. Scattered production in Argentina, Peru, Spain, Japan and Germany probably totals less than 100 tons per year.

Selling. Metal for pharmaceutical preparations must be more than 99.9 per cent. pure and contain no arsenic. That used for alloys is not so rigidly specified but in general must contain at least 99.9 per cent. Bi. Price is substantially fixed by Johnson, Matthey & Co., London, and fluctuates but little. Pre-war price was \$1.50 @ \$2.00 per lb. It rose to \$4.00 during the war. *Eng. & Min. Jour.-Press* (Oct. 3, 1925) quotation was \$2.65 @ \$2.70 in ton lots. These prices could not be maintained in the face of large increase in production. The market form is 25-lb. ingots.

Treatment. Domestic sources are lead- and tin-refinery slimes. At the S. AND M. tin-tungsten mine in Tasmania and the BURMA QUEENSLAND CORP. (tungsten-molybdenum mine) in Australia (see "Tungsten") bismuth is an important part of the concentrate.

9. Cadmium, Cd

Properties. Metal; bluish-white, lustrous; soft, malleable, ductile (see also Table 1). AT. WGT., 112.4. Very slightly affected by air at ordinary temperature but burns when strongly heated. Decomposes water at red heat. Attacked slowly by hydrochloric and sulphuric acids, vigorously by nitric, forming corresponding salts. Ion is bi-valent, base-forming. Cadmium alloys freely with other metals.

Uses. Principal uses are in making alloys of low-fusing temperature; in electro-plating hardware, automobile parts and the like by the udylite process to resist rusting; in the standard Weston cell; and, in the form of sulphide, as a yellow or orange pigment.

Ores. Cadmium is obtained both in this country and abroad exclusively as a by-product from zinc smelting and refining, or from bag-house dust at

lead smelters where zinc is a constituent of the ores treated. Siebenthal (*MR, 1921*) states that cadmium occurs in all zinc ores in the proportion of about one of cadmium to 200 of zinc.

Production (*MR*). United States and Upper Silesia are the principal producers. Domestic production ranged from 54,000 lb. of metal and 17,000 lb. of sulphide in 1913 to a peak of 207,000 lb. of metal and 50,000 lb. of sulphide in 1917. Following a slump, the metal production in 1922 was 132,000 lb. and the sulphide 135,000 lb. Upper Silesian production of metal in 1913 was 82,000 lb. and in 1922, 55,000 lb.

Selling. The commercial metal is in the form of pencils of 99.5 per cent. standard purity but most of the metal marketed runs higher, up to 99.9 per cent. The sulphide ranges from 98 to 99.9 per cent. pure. Prices of metal and sulphide usually keep within 5 or 10¢ per lb. of each other. Metal price in 1913 was $0.77 per lb.; the peak in 1916 was $1.56; quotation (*Eng. & Min. Jour.-Press*) Oct. 3, 1925, was $0.60 per lb. Demand is growing rapidly but at present the potential supply is in excess of the demand, the market is highly competitive and prices are generally falling.

Treatment. Dry method: Crude metal is obtained by fractional distillation from blue powder and this metal is refined by further fractional distillation. Wet methods consist in solution of cadmium oxides in acids and precipitation of the cadmium either chemically or electrolytically. (For full discussion see Hofman, *Metallurgy of zinc and cadmium, McGraw-Hill Book Co., N. Y.*)

10. Chromium, Cr

Properties. Metal; gray-white, lustrous, crystalline structure, very hard. (See also Table 1.) AT. WGT., 52.0. Unchanged in air at ordinary temperatures; at red heat becomes slowly coated with a thin layer of oxide. Dissolved by dilute hydrochloric and sulphuric acids with formation of corresponding salts. Nitric acid does not attack it. Chromium ion is bi-, tri- and quadri-valent, base- and acid-forming. Chromium alloys freely with other metals.

Uses. Pure metallic chromium is not used commercially. Ferrochrome, an alloy composed chiefly of iron and chromium with small amounts of carbon, silicon, and other impurities, notably manganese, is widely used for hardening steel for railway-wheel tires, wearing parts incrushing machinery, and other steels where toughness and hardness are essential. Chromite bricks are highly refractory and are used for furnace linings. Chromates and bichromates are largely used as red, yellow, and green pigments for dyeing, calico and wall-paper printing, painting, and pottery. Chromium compounds are largely used in tanning and to some extent in medicine. Recently "stainless" steel and "rustless" iron, both containing 12 to 14 per cent. chromium, have come onto the market and will, with increasing use, increase chrome consumption. Chromizing by a process similar to zinc sherardizing and aluminum calorizing has been accomplished and chromium plating has also been effected. Both chromized and chrome-plated iron and steel resist atmospheric corrosion and the latter resists acid and ammonia fumes but not electrolytic corrosion in mineral acids. (*32 MI 118.*)

Ores. Chromite ($FeO \cdot Cr_2O_3$) in highly basic igneous rocks or in serpentine is the only ore. The natural mineral is rarely pure chromite, Cr_2O_3 being replaced by Al_2O_3 or Fe_2O_3. As a consequence the highest grade of ore contains only about 55 per cent. Cr_2O_3 and the Cr_2O_3 content in salable ores runs down from this figure to 38 to 40 per cent.

Production by countries is given in Table 13. Domestic production during wartime was all from small, not particularly high-grade deposits, mostly located in the west, many of them remote from transportation facilities. Under normal conditions of world trade, with consumption within a few hundred miles of the Atlantic seaboard, domestic production from the

West cannot compete with ore from Rhodesia and New Caledonia and there are no eastern deposits of sufficient size and purity to supply the demand.

Table 13. World production of chromite, metric tons. (*MR*)

a Includes Austria-Hungary, Australia, Great Britain, Guatemala, Norway, Yugoslavia, Union of South Africa. *b* Figures not available. *c* Not complete.

Selling. Chromite is usually sold on the basis of the long-ton unit (1 per cent.) of Cr_2O_3 and the price per unit increases with the Cr_2O_3 content, but ore for refractories is sold at a flat price with a guaranteed minimum chromic-acid content. *Eng. and Min. Jour.-Press* quotation, Oct. 3, 1925, was: "Crude, 45 to 50 per cent. Cr_2O_3, \$20.50 @ \$23.50 per net ton, f.o.b. shipping point. . . . Ground, in bags, \$29. New Caledonian, 52-54 per cent. Cr_2O_3, \$24; nominal." Average yearly price per long ton for domestic sales was \$11.19 in 1913, reached a peak of \$47.99 in 1918, and has since receded, with some fluctuation, to a range between \$18 and \$24.

Treatment. The foreign ores are mostly from high-grade deposits that require no concentration other than hand sorting. Chromium ores respond to simple gravity concentration and some such concentration is necessary with many of the domestic ores. A 50 per cent. Cr_2O_3 concentrate can readily be obtained unless the chromite itself is of too low grade.

11. Clay

Properties. Clay of commerce is not a definite mineral, but rather a mixture of minerals in which one with unctuous feel and plastic consistency predominates and imparts its physical aspect to the mixture. The predominating mineral is ordinarily kaolinite, a hydrous aluminum silicate ($2\ H_2O \cdot Al_2O_3 \cdot 2\ SiO_2$) formed by decomposition of feldspars, but it may be some other closely related hydrous silicate of aluminum such as halloysite or bentonite. The usual associated minerals are quartz and feldspar, mica, calcite, gypsum, limonite, and some of the more resistant minerals of the original feldspar-bearing rock, such as garnet, beryl, tourmaline, hornblende, titanite and ilmenite. Kaolinite is normally white but may be tinged gray, yellow, brown, blue or red by impurities. SPECIFIC GRAVITY is about 2.6; HARDNESS, 2 to 2.5. *Ladoo* gives the INDEX OF REFRACTION as 1.561; MELTING POINT, 1850° C; and says that it is soluble in hot sulphuric acid. Important physical properties depend upon use. Clays for fillers should be very fine-grained, free from grit, white in color, with low oil-absorption. For ceramic use plasticity, cohesion, shrinkage and behavior as to cracking when dried, tensile strength, porosity, and disintegration in water are important. Behavior on heating, particularly as regards shrinkage and cracking, and the character of the burnt clay, its tensile strength, porosity, absorptive capacity, color, translucency, hardness and toughness are important in ceramic use. The requirements of clay-using industries are so varied and the requirements of any particular industry so difficult, if not impossible, of quantification, that the only safe way to determine the value of the clay in a given deposit is to submit samples to prospective users.

Uses. High-grade clays are used for porcelain, china, pottery and high-grade tile; as a filler in paper, paint, linoleum, oilcloth, rubber, soap, asbestos products, plaster, cloth and a large variety of other materials and as a fire refractory for metallurgical and other furnace linings. Bentonite has a special field in de-inking newsprint. Lower-grade clays and clayey shales are used for terra-cotta ware, vitrified pipe and tile and brick of all kinds.

Ores. Deposits of low-grade clays are found in substantially all parts of the world. Deposits of high-grade clays are less abundant and extensive and are much less widely scattered. Those of the United States are almost all in the eastern and southern states. There are also important deposits in England, France, Germany and Austria.

Production of high-grade clays in the United States ranges between two and three million tons per year. Price range is from $1 per short ton for some high-grade brick clays to $12 or $15 average for kaolin. The production of low-grade clay is not available but is far in excess of the above figures.

Selling. There are no standard specifications. Clays are ordinarily sold on the basis of samples submitted to the purchaser. There is, consequently, no open market and price is a matter of individual arrangement between the producer and consumer.

Treatment (*Bul. 53, USBM*) consists in disintegrating, settling out the impurities in water, dewatering and drying. Refined lump clay that is to be used for fillers and like purposes must be again pulverized. A flow-sheet of a typical plant is shown in Fig. 6. Rake and bowl classifiers and continuous thickeners would undoubtedly give cheaper and better service than the crude settling and dewatering devices used.

a, See Fig. 7. Approximately 3 × 3 × 10 ft., 200 r.p.m. Usually two are placed in series. ***b***, See Fig. 8. Tank about 10 ft. long and 6 ft. high. Sand scooped up by shovel arms is drained in rising and discharged over the side of the box. Frequently two are placed in series or the flow is from the primary washer to a sand wheel, thence to a secondary washer and sand wheel. ***c***, There are two types: (1) The broad trough, about 2 ft. wide by 20 to 30 ft. long, set level, with a discharge baffle 4 to 8 in. high. (2) The square tank, 6 ft. long, 5 ft. wide, 1 ft. deep with outlet 3 in. below the inlet and located either at one side or at the inlet end. ***d***, U-shaped troughs about 1 ft. wide × 1 ft. deep × 40 to 50 ft. long, arranged either in series (U. S. practice) or radiating from a central basin and flared toward the discharge end (British practice). In the series arrangement the troughs are either set level with a drop of 1 in. from trough to trough, or each trough is sloped 1 in. in its length. Operation is periodic. Usual procedure is to run pulp for about 5 hr., then cut off feed, run clear water for 15 or 20 min., then close regular outlet, open waste outlet, and scrape and flush the sediment therethrough. About 1 hr. is required for this cleaning.

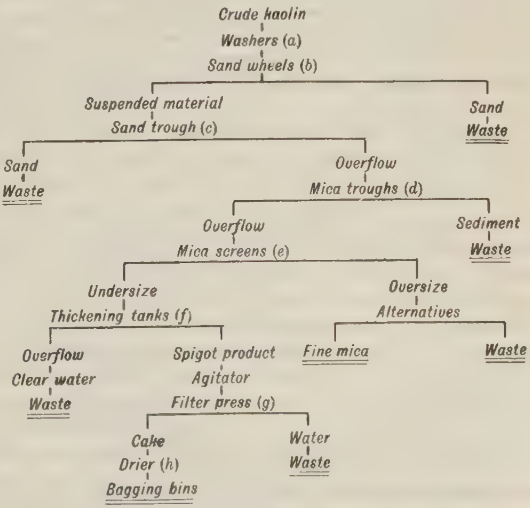

Fig. 6.—Typical kaolin-washing plant.

e, Stationary, vibrating, sliding and revolving screens are used. Usually 3 or more of the stationary screens are used in series, set at about 10° slope with 6-in. drop between screens. Screens are covered with fine brass cloth. *f*, Called locally "concentrating tanks." Lump alum, suspended in a bag in the feed launder, is commonly used as a flocculator to aid settling. The tanks are ordinarily intermittent and clear water is siphoned off. *g*, 100 to 120 lb. per sq. in. pressure. Cake contains 8 to 20 per cent. water. *h*, Atmospheric drying floors, unheated or steam-heated, or a drying tunnel through which air heated by passage over steam pipes is drawn, are used.

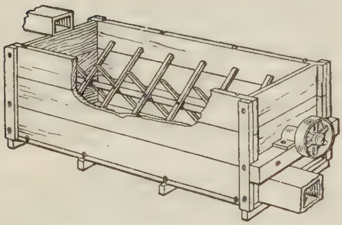

FIG. 7.—Kaolin washer.

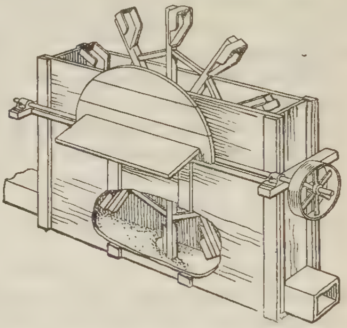

FIG. 8.—Sand wheel for clay washing.

12. Coal

Definition. In the present state of knowledge it is impossible to give an accurate, comprehensive definition of coal. What is known is that coal is a black or brown, rock-like, combustible substance, composed principally of carbon in various solid, liquid and gaseous compounds with hydrogen, oxygen and nitrogen and that any given mass represents a stage in a long series of complex geochemical transformations that start with dying and decaying vegetable matter and may end with graphite as the only residual solid product. The identities of the carbon compounds in different coals probably differ, certainly the proportions of the different compounds differ, but there is little or no exact knowledge of the composition of these compounds. In addition to the carbon compounds, coal also contains sulphur in various combinations, *e.g.*, pyrite, gypsum and unknown carbon compounds; water, and non-combustible "ash," this latter being principally silica or various silicates, carbonates of calcium, magnesium and iron, and minor amounts of various other mineral salts such as alkaline chlorides and calcium phosphate.

Rank. As above stated, coal has been derived by geologic processes from vegetable matter that has suffered slow decay and consolidation at or below water level, followed by further consolidation and metamorphosis due to the pressure and heat incident upon deposition of overlying strata and subsequent elevation and folding. These processes have been continuous and of varying intensity, through many geologic ages up to the present time, so that coal is found in all stages from the growing plant to graphitic carbon. The coal material in these various stages has different compositions and physical properties and widely different degrees of usefulness. As a result a rough classification of coals has developed, founded principally on use, but approximately expressible in terms of chemical analysis. The place of a given coal in this classification is called its RANK. There is no generally accepted classification according to rank.

Table 14 gives the classification in common use in U. S. Geol. Survey publications (*100–A USGS 3*). A somewhat more complete classification proposed in *The coal resources of the world* (*1913*) is summarized in Table 15. A classification proposed by Ashley (*1923 Pro. CMIA 29*), which further subdivides the bituminous rank on the basis of use, is given in Table 16. Several other classifications are summarized and discussed by Ashley in the last-named publication. Campbell (*Prof. Paper 48, USGS, Part I, p. 156*) discusses several possible bases of classification. The range in chemical analysis of coals of various ranks, as given by Moore (*Coal, John Wiley & Sons, 1922*), is shown in Table 17.

Properties of coal differ considerably with its rank.

Anthracite is brittle, grayish-black to black with dull to sub-metallic luster. HARDNESS varies from 2 to 2.5. It breaks with distinctly conchoidal FRACTURE, with sharp edges. SPECIFIC GRAVITY of low-ash particles ranges from 1.3 to 1.7 and rarely to 2.2 (Rhode Island) (*Bul. 615, USGS*). It ignites with difficulty and burns slowly without much disintegration, with a short hot flame and little smoke or odor. It does not coke.

Semi-anthracite is similar in appearance to anthracite but softer, and the FRACTURE is less distinctly conchoidal. SPECIFIC GRAVITY is about 1.4. It ignites more readily than anthracite, crumbles to some extent in burning and hence burns more rapidly, with a short, yellow flame. It does not coke.

Bituminous coals vary in COLOR from dark brown to black and in LUSTER from dull to resinous or brilliant. HARDNESS is less than anthracite, but on account of the brittle and

Table 14. Classification of coal. (*U. S. Geol. Survey*)

Rank	Fuel ratio	Approximate moisture, per cent. (*a*)	Physical characteristics
Anthracite	10–60	2–3	*b*
Semi-anthracite	6–10	3–6	*b*

a Average. *b* As cut. *c* Usually. *d* 5500 to 7000 un-dried; 10,000 to 12,000 on moisture-and-ash-free basis.

crumbly nature of many varieties, is difficult to test. The FRACTURE is usually along planes of weakness in two or three directions at substantially 90° to each other, resulting generally in the formation of cubical and rounded lumps. SPECIFIC GRAVITY of low-ash particles ranges from about 1.15 to 1.35.

Semi-bituminous coal is only slightly lower in the scale than semi-anthracite and is similar to it in appearance and structure but on account of the higher content of volatile matter, ignites more readily and burns more rapidly. It may coke but the coke is small and weak. Mixed in proper proportions with a good coking coal it may, however, strengthen the resulting coke. U. S. Navy specifications for Pocahontas coal are for the following maxima: moisture (as received), 2.5 per cent.; ash (dry basis), 6.5 per cent.; sulphur, 0.75 per cent.; volatile matter, 22 per cent.

Coking coal is a bituminous coal, usually brilliant black, of crumbling structure, containing from 20 per cent. to upwards of 40 per cent. volatile matter. It has the property of softening, when gradually heated in a closed container to the point of incipient decomposition (300 to 400°C), and forming a pasty mass which swells, with evolution of gas, and before 450°C is reached becomes a rigid, porous, combustible, carbonaceous solid. The phenomenon is called COKING and the solid product is COKE.

The greatest USE for coke is as a fuel in iron blast furnaces. For such use the coke should be strong, porous and in the form of large lumps and should contain, in general, less than 1.5 per cent. sulphur and less than 12 or 13 per cent. ash. Usually 1.0 per cent. is the maximum sulphur allowance and, if the coke is to be used for making acid open-hearth or Bessemer iron, the phosphorous content should not exceed 0.010 per cent. In coke for making basic iron and foundry iron the phosphorous content is relatively unimportant. Coke for non-ferrous smelting may contain more sulphur.

A good coking coal yields from 65 to 75 per cent. of its weight in the form of coke. This coke contains all of the ash that was present in the coal and, frequently, from 50 to 60 per cent. of the sulphur, hence there is a concentration of ash and, usually, some elimination of sulphur in the process of coking, and the allowable sulphur and ash contents of the coals are to be calculated accordingly. The specifications for the best inland slack trade for coal for by-product coking are: Moisture (as received), 5 per cent. max.; ash (dry basis), 7 per cent. max.; sulphur, 1 per cent. max.; volatile matter, 20 per cent. min. (*MCJ., Jan., 1926.*) If the removable ash content of the coal is in the form of shale particles, these form centers for radiating cracks in the resultant coke, and thus decrease its compressive strength.

It is generally figured that, on the basis of pre-war prices, each unit of ash in the coke adds approximately $0.20 per ton to the cost of pig iron obtained therewith, this increased cost being due to (*a*) the increased amount of limestone flux required to slag off the ash, (*b*) the greater volume of coke, limestone and slag to be handled, and (*c*) decreased furnace output (*18 CA 1130*). Sulphur adds similarly to the cost of pig iron. Sweetser stated that with pig iron costing $20 per ton, each reduction of 1 per cent. in the ash content of coke reduced the cost of the pig iron $0.30 per ton.

In general, the only sure method of determining whether a coal is suitable for coking is actual trial (Rose, *A*, *Feb., 1926*). White (*Bul. 29, USBM*) has called attention to the fact that in the best coking coals the ratio H/O is upward of 58. Some coals with a ratio of 55 to 58 make satisfactory cokes, and many with a ratio less than 55 coke, but the coke is weak and unsatisfactory. Pishel (*1908 AGLJ 445*) states that when bituminous coal is pulverized in an agate mortar, the pulverized material adheres to the mortar strongly and persistently if the coal is a good coking coal, otherwise the powder can be readily collected in the bottom by tapping the mortar.

Gas coal is a variety of coking coal containing usually from 33 to 38 per cent. volatile matter (dry basis) and yielding, on coking, a gas of high calorific value. The sulphur content should be low (less than 1.25 or, frequently, less than 1 per cent.), in order to keep down the amount of hydrogen sulphide in the oven gases, since this must be scrubbed out completely before the gas is put into the mains.

Classification of coking coals. Figs. 9 and 10, presented by Rose (*A*, *Feb., 1926*), permit tentative placing of a bituminous coal, knowing either the ultimate analysis (Fig. 9) or the calorific value and volatile matter (Fig. 10), it being remembered in all cases that the final proof is the full-scale oven test.

For thorough discussion of "The selection of coals for the manufacture of coke" see H. J. Rose (*A*, *Feb, 1926*).

Non-coking coal may be similar in appearance to the coking variety, although the term includes also varieties of bituminous rank that have a splintery fracture (SPLINT COAL), certain dull varieties, etc. Non-coking coals are used principally for steam

generation and for this purpose the important characteristics are the heating value per unit weight of ash-free coal and the kind and amount of impurities. The ash should be of such composition that it will slag sufficiently to permit a bed of ashes to be maintained on a grate, but not so readily fusible that clinkers (fused ash) form in sufficient size and quantity to make removal difficult. A higher sulphur content is permitted than in coking coal and it is the pyritic sulphur that is of most importance. The principal disadvantage of high pyritic sulphur is the fact that the iron oxide formed by its decomposition may lower the fusing temperature of the ash and thus cause too much clinkering. For analyses, see Table 17.

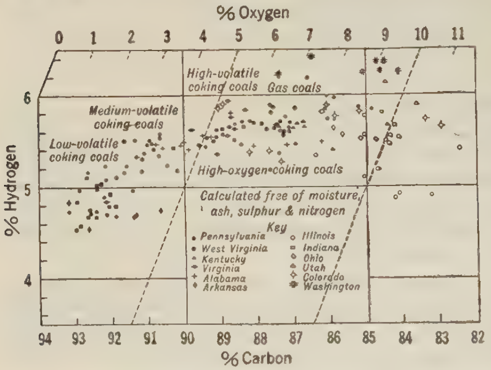

FIG. 9.—Ultimate analyses of 150 typical coking coals of the United States.

Sub-bituminous coal is the transition rank between lignite and bituminous coal. The FRACTURE is usually along one plane or, sometimes, conchoidal, so that it tends to break into slabs rather than into the cubical forms characteristic of the bituminous rank. The color is black and the luster glossy to resinous. (See also Table 17.)

Lignite is a brown, amorphous or woody form of coal representing the least change from peat. The luster is generally dull. SPECIFIC GRAVITY varies from 0.5 to about 1.3, according to the porosity (woodiness) and the amount of impurity. For analyses see Table 17.

Impurities in coal occur in several different varieties and forms. The impurities are classified as sulphur and ash.

Sulphur ranges between 0.5 and 8 to 10 per cent. of the coal as mined (*20 CA 3*). It occurs in three forms, *viz.*: as pyrite, as a sulphate, usually calcium sulphate, and in an organic combination. There is no constant relation between the amounts occurring in the different forms. Table 18 shows the results of sulphur analyses on typical coals from various domestic fields.

Ash content varies from 1 to 30 per cent. (*20 CA 3*). The ash occurs in several different forms: (*a*) As INHERENT ASH, which represents various inorganic minerals, principally silicates, so intimately associated with the coal as to be substantially inseparable therefrom by any mechanical means; X-ray examinations indicate that this ash consists of submicroscopic laminae of inorganic material alternating with thicker laminae of pure coal. (*b*) As RASH OR MOTHER-OF-COAL, which is a dull amorphous carbonaceous material of low specific gravity, but high inorganic content, found in bituminous coal. (*c*) In masses composed of fine inter-laminated layers of good coal and shale or slate so closely associated that fine crushing is required to separate them; these are known as BONE OR BONEY COAL. SULPHUR BONE is a similarly intimate mixture of pyrite and good coal. (*d*) As distinct masses of shale (with bituminous coals) or slate (with anthracite), clay, or other rocks which break

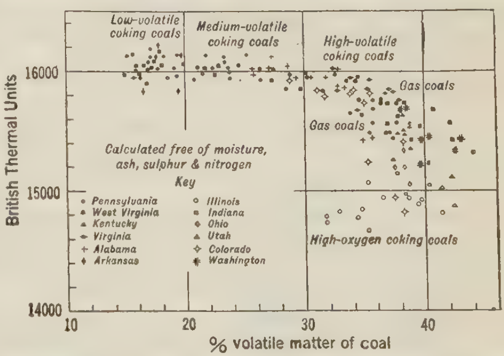

FIG. 10.—Volatile matter and calorific value of 150 typical coking coals of the United States.

cleanly away from the coal. (*e*) As crusts and veinlets of certain salts, of which the most important are sodium chloride and calcium phosphate.

Table 18. Forms of sulphur in raw coal. (*Bul. 11, UI*)

Coal from	Percentages of sulphur			
	Total	Pyritic	Sulphate	Organic
Tennessee	4.87	3.59	0.11	1.17
Kentucky	0.46	0.13	....	0.33
Illinois	1.83	1.04	Tr.	0.79
Illinois	3.51	1.84	....	1.67
Indiana	1.66	0.89	....	0.77

The important property of ash, apart from the fact that its presence lessens the heating value of the coal, is its fusibility. (For complete discussion see Fieldner and Selvig, *PP 1529-F A*)

Uses of coal. The principal uses are for fuel and as the source for a large number of important products derived by distillation. Anthracite is used principally for domestic fuel, but some large-size anthracite is used in gas producers and locomotives and the small sizes (buckwheat, rice and barley) are used for steam production in power plants. Table 19 shows the approximate distribution, according to use, of the soft coal consumed in the United States and exported in the year 1917. Fig. 11 shows some of the products obtained by distillation of bituminous coal.

Table 19. Consumption of soft coal in the United States, classified according to use (1917). (*After Tryon and McKenney, 21 CA 85*)

Use	Short tons	Per cent of total
Railroads	153,700,000	27.7

Totals	554,200,000	100.0

a Excluding by-product ovens.

Grades of coal as mined vary all the way from those sufficiently pure to be used with no treatment other than that required to bring them to suitable size, to grades so impure as to be economically impossible of exploitation. This statement holds for all of the different ranks. (See also **Treatment.**)

Production of coal in the United States in recent years is given in Table 20. The domestic production in 1924 was about 38.5 per cent of the world production (1,350,000,000 metric tons). The other principal producing countries in 1924 were Great Britain, 20.3 per cent.; Germany, 8.8 per cent.; France, 4.3 per cent.; Poland, 2.4 per cent.; and Belgium, 1.7 per cent. These countries stood in the same order in 1913. The remaining 24 per cent. of world production was from 44 countries scattered on all of the continents.

Selling. Notwithstanding the huge demand for coal, as evidenced by the consumption figures, the price at domestic mines for ordinary grades is kept

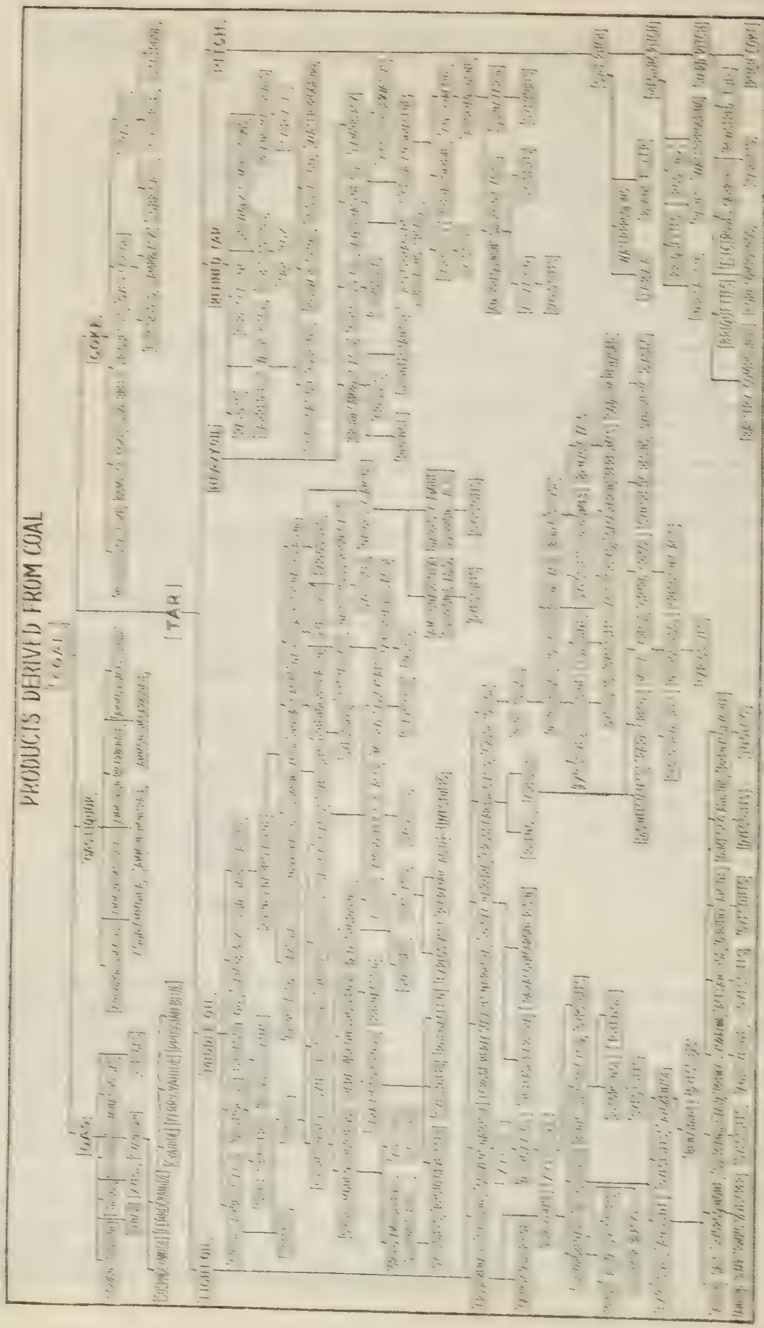

Fig. 11.—Products from the distillation of coal (after Barrett Mfg. Co.).

down by the excessive potential production capacity, close competition, and the high freight charge when distant shipments are necessary. These conditions apply less to anthracite than to bituminous coals, on account of the superiority of anthracite for domestic fuel, but in regions where a good grade of bituminous coal is locally available for domestic fuel, even anthracite suffers from the competition. Certain types of bituminous coal occupy a favored position because of their unique suitability for exacting uses. High-volatile coking coals (upwards of 30 per cent. volatile matter) which will yield upward of 10,000 cu. ft. of gas per short ton and contain less than 1 to

1.25 per cent. sulphur are in demand for gas works. High-volatile non-coking coals are demanded for locomotives pulling heavy, fast trains. Semi-bituminous coal (SMOKELESS COAL) makes the best kind of steam coal. This and semi-anthracite compete with anthracite for domestic use. Coals suitable for iron-furnace coke enjoy a marked preference over other bituminous grades. Other users with special requirements are malleable-iron furnaces, brick yards, and blacksmiths. (For a general analysis of markets see *Spurr and Wormser.*)

Prices of domestic sizes of anthracite (Table 21) are reasonably stable, due to the constancy of demand and close control of the major part of the total production. With the exception of a seasonal drop of about \$0.50 per ton in April, which, prior to 1916 was customary but has occurred only twice since, there has been a steady increase in average price since 1915 from \$3.75 per gross ton at the mines in that year to \$9.00 at the end of 1924 (N. Y. quotations). The so-called INDEPENDENT MINES (meaning small individual mines or groups which in all produce about 30 per cent. of the total output and sell on day-to-day quotation rather than on contract, as do the large COMPANY MINES or groups) have averaged considerably higher in their returns than the company mines, and for short periods have received much higher prices. For example, in the fall of 1916, the price of independent coal rose above \$8.00 against \$4.35 for company coal, and in the fall of 1920 the corresponding prices were \$14.25 and \$8.00. On the other hand, since Jan., 1916, the only time that the independent price has fallen below the company price was in Apr., 1919, when there was a spread of about \$0.25 per ton.

Table 21. Approximate sizes of market grades of anthracite

Name of size		Size of round opening, inches	
		Passing	Retained on
Domestic sizes	Lump	....	6
	Steamboat	6	4½
	Broken (grate)	4½	2¾–3¼
	Egg	2¾–3¼	2¼–2⁵⁄₁₆
	Stove	2¼–2⁵⁄₁₆	1½–1⅝
	Chestnut	1½–1⅝	⅞–1
Steam sizes	Pea	⅞–1	½–⅝
	No. 1 Buckwheat (*a*)	½–⅝	¼–⁵⁄₁₆
	No. 2 Buckwheat (Rice) (*a*)	¼–⁵⁄₁₆	⅛–³⁄₁₆
	No. 3 Buckwheat (Barley) (*a*)	⅛–³⁄₁₆	⁵⁄₆₄–⅛
	Culm	³⁄₃₂–⅛	....

a These three sizes are sometimes mixed under the name "Birdseye."

Prices. Steam sizes of anthracite (Table 21) compete with bituminous coal and are subject to the same fluctuations. For four years prior to 1917, the company price was substantially constant at close to \$1.60 per long ton at the mines. Since then it has risen to a maximum of about \$4.10 in the fall of 1920 and again in the fall of 1922. During the summer of 1924 the price was about \$3.05. Independent prices have averaged slightly higher with spreads of about \$2 per ton in their favor in the fall of 1916 and 1920.

The average value per gross ton of anthracite in 1923, with due weighting for value and amount of domestic and steam sizes, local trade and mine fuel was \$5.43 in 1920 and \$6.08 in 1923. (*33 MI 137*).

Bituminous-coal prices fluctuate widely with seasonal demand and with variation in the industrial activity of the country. Furthermore, as set forth above, the price varies widely according to the grade. Fig. 12 shows the extent of the fluctuation in the years 1913 to 1924 incl.

Preparation

The treatment required to prepare coal for the market depends on the character of the material delivered from the mine and the demand of the particular market supplied. All anthracite requires some prepa-

ration, if only crushing and sizing, and much of it, as now mined, requires separation of impurities such as slate and bone. Much bituminous coal, on the other hand, is sold as mined or is given only the crudest kind of screening. Only between 5 and 10 per cent. of the total bituminous production is subjected to a concentrating treatment.

	1924 Dec. 29	1924 Dec. 22	1924 Dec. 15	1923 Dec. 31
Index	171	170	169	170
Weighted average price	$2.07	$2.06	$2.04	$2.17

This diagram shows the relative, not the actual, prices on fourteen coals, representative of nearly 90 per cent. of the bituminous output of the United States, weighted first with respect to the proportions each of slack, prepared and run-of-mine normally shipped, and second, with respect to the tonnage of each normally produced. The average thus obtained was compared with the average for the twelve months ended June, 1914, as 100, after the manner adopted in the report on "Prices of coal and coke; 1913–1918," published by the Geological Survey and the War Industries Board.

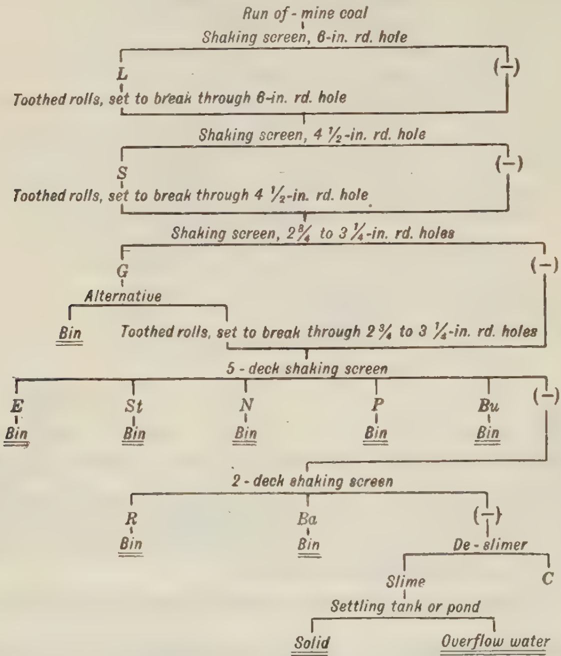
Fig. 12.—Coal Age index and spot prices of bituminous coal f.o.b. mines.

Preparation of anthracite. The principal impurity is shale or slate, which occurs generally in flat and elongated slabs and plates, is dull gray to black in color, and has a specific gravity between 2.5 and 2.7. Anthracite breaks into generally rounded lumps, its color is lustrous black and its specific gravity ranges between 1.3 and 1.7. The bone or middling particles consist of mixtures of coal and slate in all proportions. When the amount of bone is small, picking and gravity concentration are both relatively easy to apply. In hand picking the pickers are guided by the distinctive shapes, and, if the feed on the picking surface has been properly washed, by a distinctive color difference. If bone also is picked, the separation is more difficult, as both shape and color range between the extremes of rock and slate. However, since the bone is to be crushed and further treated, doubtful cases may be consistently resolved in favor of the bone circuit, with consequent increase in picking rate.

Separation of slate from anthracite by gravity concentration is relatively simple. The free-settling ratio (Sec. 6, Art. 1) of coal and slate is $D_{\text{coal}}/D_{\text{slate}} = (2.5 - 1)/(1.5 - 1) = 3.0$. Since market requirements demand sizing to a considerably closer sieve ratio than 3 : 1, (see Table 21), if the sizing is done prior to jigging, subsequent separation is simpler than that met with in most metal-concentrating mills. On the other hand, when there is

much bone present, the free-settling ratios become much smaller and separation is correspondingly more difficult.

For high-grade coal such as may be obtained from thick, horizontal or slightly inclined seams, treatment may consist of nothing more than crushing and screening to prepare the market sizes. In a breaker for such service the flow-sheet is essentially as shown in Fig. 13.



Ba, Barley size. ***Bu***, Buckwheat size. ***E***, Egg size. ***G***, Grate size. ***L***, Lump size. ***N***, Nut size. ***P***, Pea size. ***R***, Rice size. ***S***, Steamboat size. ***St***, Stove size.

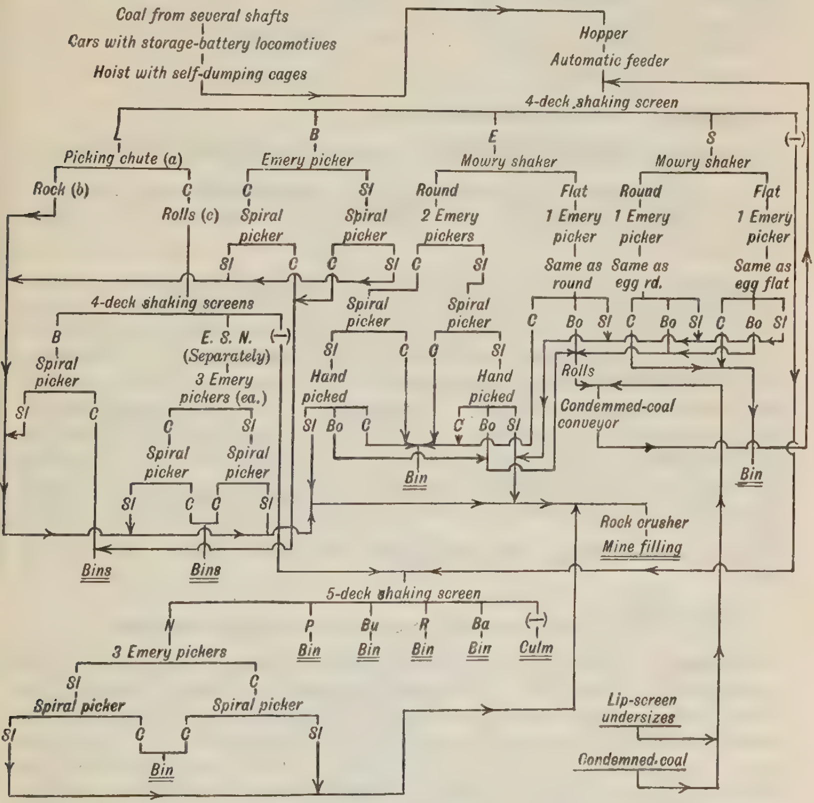
FIG. 13.—Typical pure-coal anthracite breaker.

Such breakers are substantially non-existent at the present day, but the figure illustrates the fundamental principle of arrangement of the apparatus for graded crushing and screening so as to produce the maximum amount of DOMESTIC-SIZE COAL (egg to chestnut sizes, inclusive) and to deliver all products with as little fine undersize as possible. Thus the coarse sizes are crushed separately one size-stage at a time, shaking screens are used in preference to other types, on account of the small amount of breakage that they effect, and special retarding chutes (Sec. 20, Art. 9) should be used throughout to lower the screened products into the bins. The coal passing the barley screen is suitable, after dewatering, for briquetting or for mixing back with the STEAM SIZES (pea and finer).

When, as is ordinarily the case, the coal as mined contains varying amounts of impurities, (see p. 34), the breaker must contain more or less concentrating equipment in addition to the breaking and sizing equipment. The

usual concentrating operations are picking, either hand or mechanical; jigging, and, of recent years, tabling and heavy-fluid separation. Froth flotation and granulation are also practical from the technical standpoint and only await the perfection of methods of utilization of fine coal thus cleaned to come into common use.

The type of flow-sheet employed when concentration is necessary depends upon the character of coal coming to the breaker. If this contains a relatively



a, An extension of the upper deck of the shaker. *b*, Picked. *c*, Set to produce broken size and smaller. *B*, Broken size. *Ba*, Barley size. *Bo*, bone. *Bu*, Buckwheat. *C*, Coal. *E*, Egg size. *L*, Lump size. *N*, Nut size. *P*, Pea size. *R*, Rice size. *S*, Stove size. *Sl*, slate.

FIG. 14.—Kingston Coal Co.

small amount of slate that breaks sharply and readily from the coal, the flow-sheet will be substantially the same as that shown in Fig. 13 except that each of the sizes down to and including chestnut will be hand-picked. Fig. 14 shows such a flow-sheet. If the amount of slate is large, water concentration is employed in addition to picking, usually jigs for the sizes down to and including buckwheat and, if necessary, shaking tables for the finer sizes. Figs. 15 to 22 inclusive illustrate several different variants of such flow-sheets.

When there is much clean coal in the large sizes a primary split of run-of-mine material is commonly made at steamboat size (4½-in.), slate is hand picked from the oversize and the coal is then run down separately in a so-called pure-coal section similar to the flow-sheet in Fig. 13. When the coal contains considerable bone, this is frequently separated on the coarse-picking tables and coarse jigs and crushed down so that the combustible material finally goes into the steam sizes. All of these contingencies are illustrated in the following flow-sheets.

Kingston Coal Co., Breaker No. 4 (*18 CA 935*). **Fig. 14.**

Location: Edwardsville, Pa.

Summary: Screening and picking only.

Lehigh and Wilkes-Barre Coal Co., Wanamie Breaker (*66 A 422*). Fig. 15.

Capacity: 700 tons per hr. Two sections. For tonnage distribution see numbers in parenthesis on the flow-sheet. See also Table 22 for distribution of products at Seneca breaker of Lehigh Valley Coal Co.
Building: Steel.

Summary. This flow-sheet is typical of the arrangement for treating exceptionally clean run-of-mine coal. It is perhaps not so simple to operate as the Kingston breaker (Fig. 14), but is more flexible and will yield a cleaner product with higher recovery on all except the highest grade of run-of-mine coal. The distinguishing characteristics are: (*a*) treatment of pure coal and boney coal in separate sections; (*b*) production of all sizes, from broken to No. 3 buckwheat, from picked lump in the pure-coal section, with no cleaning after crushing; (*c*) separation of bone and waste at egg and stove sizes from the steamboat- and broken-size bone by spiral pickers alone; (*d*) use of jigs to clean egg, stove and nut sizes in the boney-coal section; (*e*) no cleaning of sizes below nut.

Phila. and Reading Coal and Iron Co., Brookside breaker (*66 A 422*). Fig. 16.

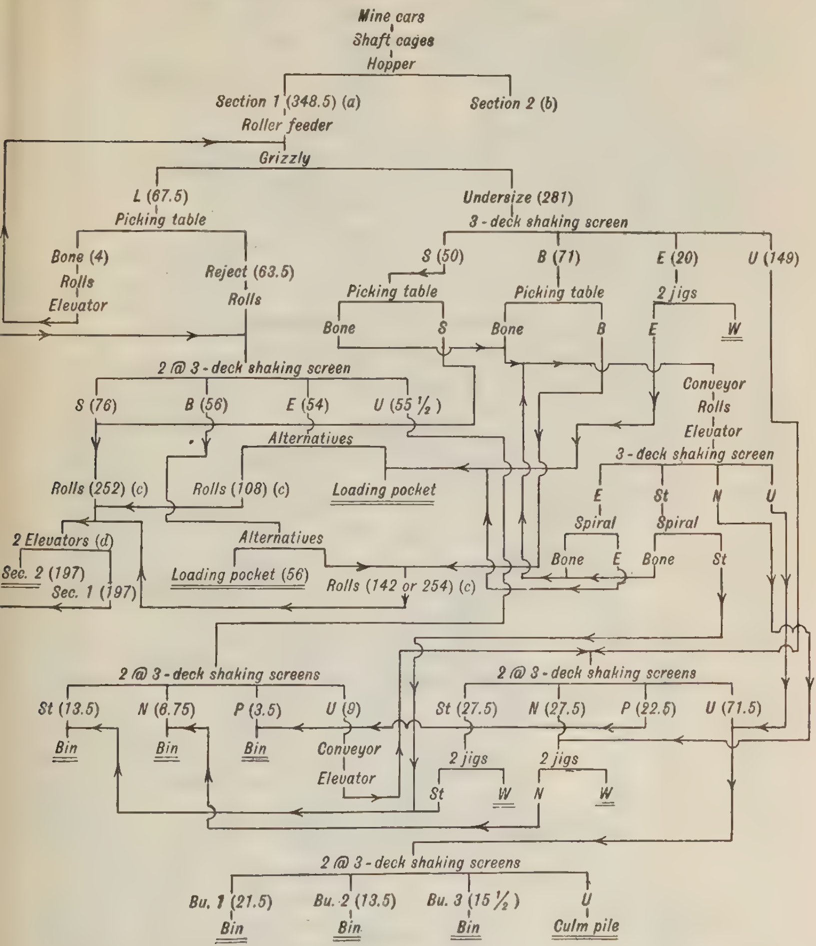
Location: Tower City, Pa.
Building: This is a hill-side breaker. A sectional drawing is shown in Fig. 17.

Summary. The coal fed to this breaker is relatively high grade. The characteristic features are: (*a*) separate pure-coal and boney-coal sections; (*b*) no cleaning in the pure-coal section following the lump-picking platform, except that the undersize of the buckwheat shakers goes to the boney-coal section; (*c*) use of jigs in the boney-coal section for all sizes from egg to rice, inclusive; (*d*) use of shaking tables for cleaning undersize of the rice shaker; (*e*) separation of egg, stove and nut sizes into flat and round grades by means of a mechanical picker prior to jigging, and separate jig treatment of the grades; (*f*) mechanical picking of the coal discharge from the egg- and stove-size coal jigs; (*g*) re-crushing of bone from the domestic-size bone jigs and pickers and return to the head of the boney-coal section.

Pennsylvania Coal Co. No. 1 (*66 A 422; 22 CA 786*). Fig. 18.

Location: Dunmore, Pa.
Building: Steel and concrete. This is a typical modern level-site breaker. See Fig. 19.
Capacity: 4000 tons per 8 hr.
Labor: 66 men per shift, as follows: 7 jig runners, 6 screen men, 34 pickers, 11 loaders, 1 machinist, 2 carpenters, 1 oiler, 3 sweepers, 1 foreman.
Estimated cost of breaker (1921–22) between $800,000 and $900,000.

Summary. This breaker is suitable for treating a lower-grade run-of-mine coal than the preceding. There is no pure-coal section. The characteristic features are: (*a*) jigging of primary sizes from grate to No. 2 nut,



a, Numbers in parenthesis are tons per hr. *b*, Duplicate of Section 1. *c*, Common to both sections. *d*, One for each section. *B*, Broken. *Bu*, Buckwheat. *E*, Egg. *L*, Lump. *N*, Nut. *P*, Pea. *S*, Steamboat. *St*, Stove. *U*, Undersize. *W*, Waste.

FIG. 18.—Pennsylvania Coal Co.

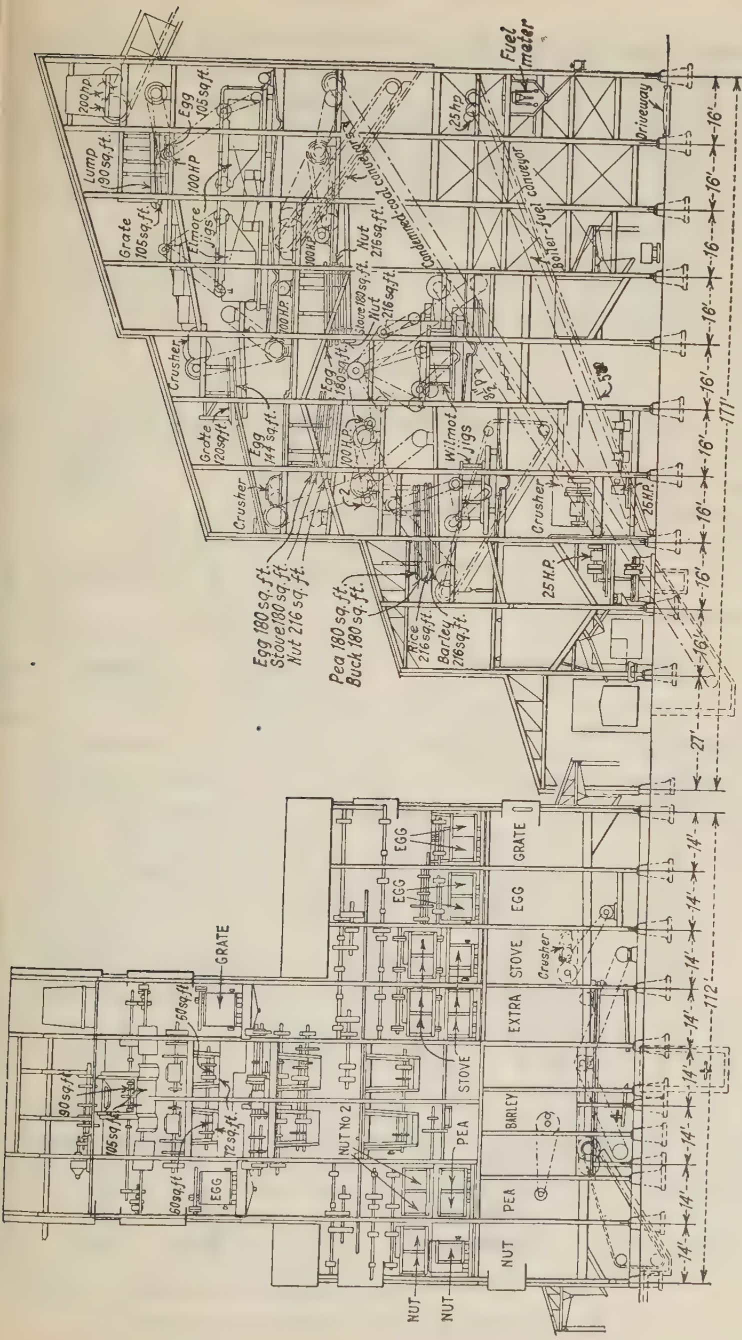

FIG. 19.—No. 1 breaker, Pennsylvania Coal Co.

Lehigh Valley Coal Co., Drifton No. 2 breaker (*59 A 335*). Fig. 20.

Location: Drifton, Pa.

Capacity: 2500 tons per 8 hr.

Labor: 1 breaker boss, 1 jig boss, 1 picking-table boss, 1 timekeeper, 2 car dumpers, 4 pickers on platform, 3 pickers on broken coal, 2 pickers on jig refuse, 2 jig runners, 4 screen and roll tenders, 1 breaker engineer, 1 oiler, 1 ropeman, 1 roustabout, 7 men loading coal.

Power distribution (approximate): Reciprocating feeder, 2 hp.; shaking screens, per deck, 2 hp.; No. 1 roll, 12 hp.; No. 3 rolls, 9 hp. ea.; 2 picking conveyors, 8 hp.; 2 elevators, 65 hp.; jigs, 4 hp. ea. Flight conveyors, 374 ft., 48 hp. Total, 272 hp. All figures include belting and line-shaft losses back to the mill engine.

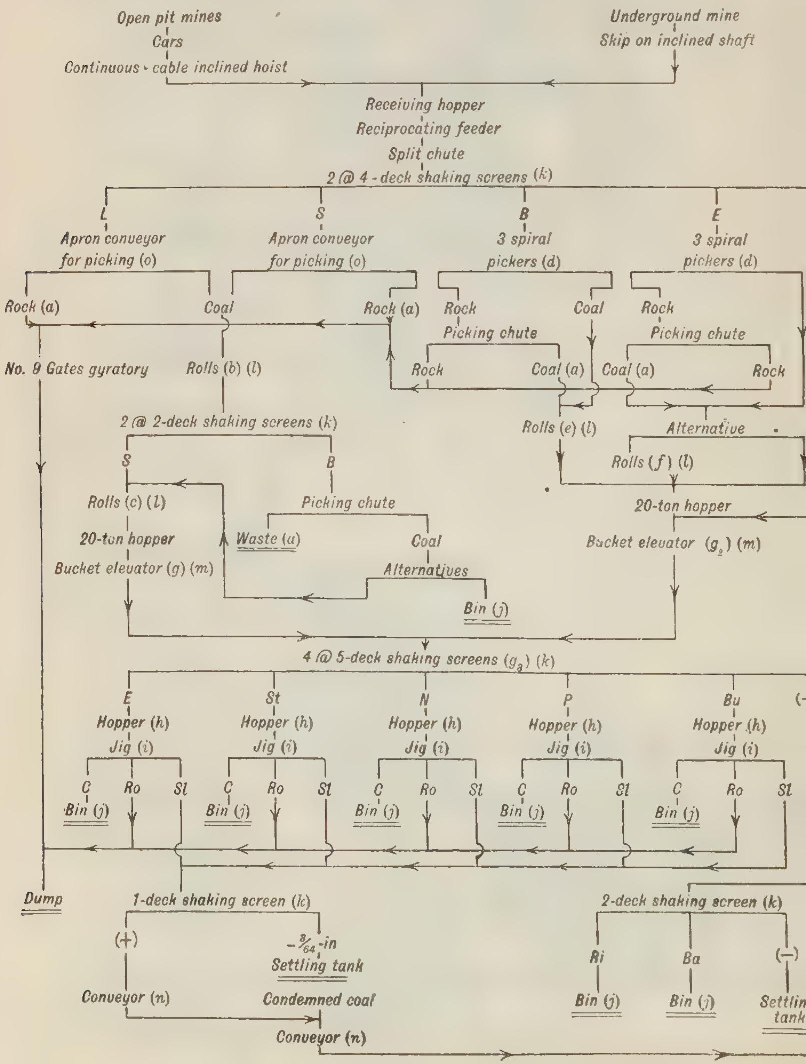

FIG. 20.—Drifton breaker, Lehigh Valley Coal Co.

a, Picked. *b*, No. 1 size. Slow speed. Set to break to broken size with a small percentage of steamboat. *c*, No. 3 size. Slow speed. Set to break to egg size. *d*, Adjusted to remove a maximum amount of rock. *e*, No. 3 size. Set to break to egg size. *f*, No. 3 size. Set to break to stove size. g, g_2, g_3, In 1917, when this breaker was first put into operation, the coal fed was very dirty and the breaker was operated as shown. It is so designed, however, that elevator g can feed two of the 5-deck shakers, which will send oversize products directly to the proper bins, thus acting as a pure-coal section, while elevator g_2 and the other two banks of shaking screens prepare impure coal for jigging. When handling 1500 to 1800 tons of feed per 8 hr., according to the flow-sheet shown, only two of the 5-deck shakers were used. *h*, With automatic discharge chute. Fed by vertical stepped telegraph (see Sec. 20, Art. 9). *i*, Simplex, 137 r.p.m. 20 jigs in all, arranged to allow diversion of feed as one or the other size of coal predominates. Tons per hour per jig on different sizes are shown in Sec. 9, Table 28. Fitted with automatic belt shifters actuated by the weight of coal in the feed chute. *j*, Fed with vertical stepped telegraph chutes. *k*, All shakers have 3 × 6-in. wood sides, 3½ × 3½ × 3/8-in. cross-frame angles, and are suspended by 1 × 6-in. hanger boards. Eccentrics have 3-in. throw. 3 × 6-in Parrish connecting arms. Decks are 4 ft. and 4 ft. 6 in. wide by 15 to 24 ft long. *l*, All rolls 36 × 36-in., compound geared, chilled cast-iron teeth. Peripheral speed 300 ft. per min. Capacity about 300 tons per hr. *m*, 22 × 25 × 12-in. buckets on two strands of 9-in. pitch, heavy-pattern chain. Bucket spacing, 18 in. Speed, 90 ft. per min. Capacity, 299 tons per hr. *n*, 6 × 18-in flights with 9-in. pitch chain. *o*, 4 ft. 6 in. wide, 30 ft. per min. Friction clutch. ***B***, Broken size. ***Ba***, Barley. ***Bu***, Buckwheat size. ***C***, Coal. ***E***, Egg size. ***L***, Lump size. ***N***, Nut size. ***P***, Pea size. ***Ro***, Rock. ***S***, Steamboat size. ***Sl***, **Slush.** ***St***, **Stove size.**

Table 22. Distribution of coal and refuse in Seneca breaker of Lehigh Valley Coal Co. (*After Ashmead, 22 CA 5*)

No.	Material or operation	Feed, tons per 8 hr.	Distribution					
			Coal			Refuse		
			Tons per 8 hr.	Per cent. of machine feed	Per cent. of breaker feed	Tons per 8 hr.	Per cent. of machine feed	Per cent. of breaker feed
1	Breaker feed	1800	......	....	....	......	....	....
2	Lump and steamboat sizes from bull shaker	216	......	....	....	26	12.0	1.4
3	Broken size, hand picked	105	70	66.7	3.9	35	33.3	1.9
4	Egg size, jigged	279	232	83.2	12.9	47	16.8	2.6
5	Stove size, jigged	377	317	84.1	17.7	60	15.9	3.3
6	Nut size, jigged	518	435	84.0	24.2	83	16.0	4.6
7	Pea size, no cleaning	117	117	....	6.5	......	....	....
8	Buckwheat size, no cleaning	138	138	....	7.7	......	....	....
9	Rice size, no cleaning	96	96	....	5.3	......	....	....
10	Barley size, no cleaning	99	99	....	5.5	......	....	....
11	Slush, to waste	45				45		2.5
12	Totals	1800	1504	....	83.7	296	....	16.3

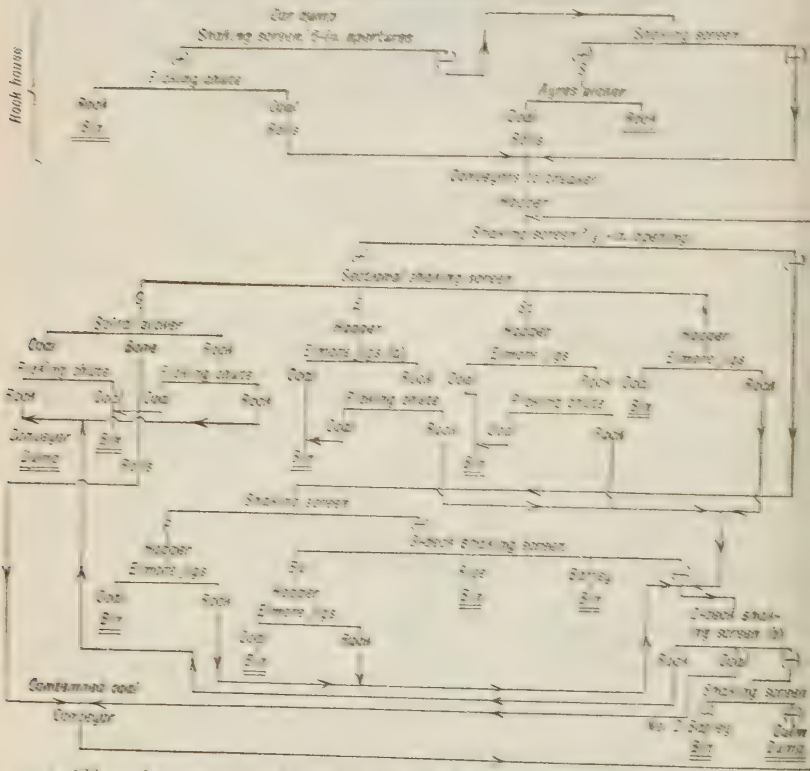
Summary. There is no pure-coal section. (*a*) Primary sizes from lump to egg are picked to reject rock, then crushed to egg size and joined with primary undersize; (*b*) all sizes from egg to buckwheat are jigged separately making finished coal and waste rock; (*c*) rice and barley sizes are not cleaned.

Lehigh Coal and Navigation Co., Rahn breaker (*66 A 422*). Fig. 21.

Capacity: 2000 tons per 8 hr.

Distribution of products.

Products	Weight, per cent	Slate in coal, per cent	Coal in slate, per cent
Grate	3.[illegible]		[illegible].0
Egg	[illegible]	2.[illegible]	[illegible].0
Stove	9.7	3.5	[illegible].8
Nut	[illegible].2	5.0	[illegible].1
Pea	10.6	8.0	[illegible].5
Buckwheat	[illegible]	[illegible]	4.1
Rice	15.3		
Barley	[illegible]		
Barley No. 2	[illegible]		



[illegible] strokes per min. [illegible] openings [illegible] Rock from the jigs [illegible] the first bank and [illegible] to the second bank. Bw, Buckwheat size. E, Egg size. G, Grate size. N, Nut size. P, Pea size. S, Steamboat size. St, Stove size.

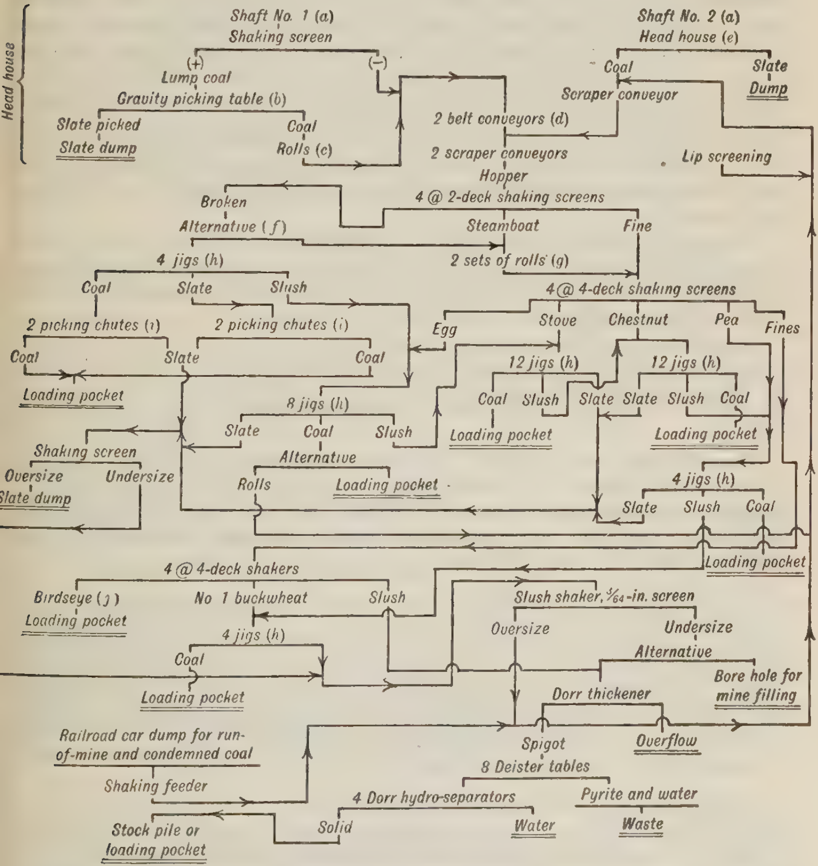
FIG. [illegible].—[illegible] breaker, Lehigh Coal and Navigation Co.

Summary. There is no [illegible] section. The characteristic features are: (a) mechanical picking at steamboat size; (b) separation of pea size

prior to separation into domestic sizes for subsequent cleaning; (c) cleaning of grate size by spiral pickers followed by hand-picking of coal from the spiral; (d) jigging of egg to buckwheat sizes; (e) hand-picking of the waste from the grate spiral and the egg and stove jigs; (f) non-cleaning of rice and barley sizes; (g) screening of the waste discharge from all jigs in order to reclaim the coal broken in jigging. The percentage of domestic sizes recovered is unusually low on account of the low grade of the breaker feed.

Hudson Coal Co., Marvine breaker (*66 A 422*). Fig 22.

Location: Marvine, Pa.
Capacity: 5000 tons per 8 hr.
Building: Steel and concrete.



a, About 2000 ft. apart. Identical equipment. *b*, Two men pick slate. *c*, Set to crush to steamboat size and smaller. *d*, 1100 ft. long. *e*, Duplicate of No. 1. *f*, Dependent upon market demand. *g*, Set to produce egg size. *h*, Delaware, piston type. (See Sec. 9, Fig. 15.) *i*, One boy on each chute. These boys are necessary in order to get clean coal and to keep coal out of the slate product. *j*, Nos. 2, 3 and 4 buckwheat mixed.

Fig. 22.—Marvine breaker, Hudson Coal Co.

Summary. There is no pure-coal section. The distinctive characteristics of the flow-sheet are: (*a*) jigging at broken size; (*b*) sizes from egg to No. 1 buckwheat, inclusive, are jigged; (*c*) material finer than No. 1 buckwheat is tabled to remove pyrite.

General summary of anthracite flow-sheets.

The characteristics common to all breakers are sizing before concentration and concentration at all sizes from +6-in. (lump) down to +1-in. (nut). With very clean run-of-mine coal, clean coal and waste slate are the only products made in each concentrating step (see the Kingston breaker). With less-clean breaker feed, bone (middling) may be taken out at the coarser sizes, but waste is rejected at all sizes from lump down and clean coal is made at all sizes from broken or egg down. (See Brookside, Pennsylvania, Drifton, Rahn and Marvine breakers.) Occasionally, as at the Wanamie breaker, rejection of waste does not start until the egg-size jigs are reached, although clean coal is taken at broken size. Concentration below pea size is the exception rather than the rule, but many recent breakers jig the buckwheat size (see Marvine, Rahn and Drifton); rice size is jigged at Brookside; and material finer than buckwheat is tabled at a number of breakers (see Marvine and Brookside).

Control of product. According to Ashmead (*21 C.A. 695*) a 50-lb. grab sample is taken from just below the surface of each carload of domestic-size anthracite. This is blown with a jet of live steam, then spread on a table where it quickly dries and is picked.

Allowances of slate and bone at HUDSON COAL CO. were: 2 per cent. slate and 4 per cent. bone in egg size; 4 per cent. bone and 4 per cent. slate in stove size, 6 per cent. slate in nut size and 10 per cent. slate in pea size. Cars failing these tests were 9.45 per cent. in March, 1922. These were dumped on the condemned-coal conveyor and returned to the plant.

Handling the coal *en route* is almost as important a part of the design of anthracite breakers as concentration, on account of the great spread in price between the domestic and steam sizes and the consequent necessity to prevent breakage. All apparatus is chosen with the view to eliminate tumbling, free fall, and rapid travel or sharp turns in chutes.

The importance of eliminating drops is shown by a test made at the breaker of the CRANBERRY CREEK CO. near Hazleton, Pa. (*18 C.A. 540*) to determine the effect of dropping run-of-mine coal 4 ft. into a chute at the head of the breaker. Results of sizing tests are shown in Table 23, indicating a reduction in tonnage of the prepared sizes of 8.4 per cent. due to the dump. At this breaker this amounted to 29,906 tons of coal out of 549,071 tons of breaker feed in 1918. During this period the average selling price of prepared sizes was $6.80 per ton against $4.18 for the smaller sizes, so that the breakage represented a loss of $2.62 per ton broken or $78,000 odd for the year. The increase in culm (slush) was 3.0 per cent., according to the table. If this is reckoned as derived from all sizes it represents 18,000 odd tons at $5.49 average price for all sizes or $99,000.

Special toothed rolls are used that break with a minimum production of fines (see Sec. 3, Art. 14). Shaking screens are preferred to revolving or fixed-inclined screens. Elevation is confined, as far as possible, to the initial entry into the breaker, and if intermediate elevation is necessary slow-speed drag conveyors are used, if possible. Bucket elevators should be employed only as a last resource, and should be arranged to load and discharge with minimum drop of material and be run at slow speeds. Special chutes are almost invariably used for lowering material from machine to

machine, whenever any considerable vertical drop is necessary, and for charging finished sizes into the loading bins. (See Sec. 20, Art. 9.)

Labor required in anthracite preparation (operating labor), as given by Ashmead (*66 A 422*) is shown in Table 24. The wet breakers employ the least men, the wet-and-dry the most.

Table 23. Breakage in dumping run-of-mine anthracite. (*After Ashmead*)

Size	Per cent. weight	
	Before dumping	After dumping
Lump	34.5	25.5
Steamboat	20.4	20.3
Broken	12.1	12.5
Egg	6.8	7.8
Stove	5.1	5.3
Nut	5.5	6.6
Pea, No. 1 Buckwheat, Rice, Barley	11.5	14.6
Slush	4.1	7.1
Total prepared sizes	84.4	78.0

Table 24. Operating labor required in anthracite breakers. (*After Ashmead*)

Percentage relation of outside employees to total employees	31.2	34.0
Percentage relation of outside employees to inside employees	44.7	50.9

Variation in labor requirement with tonnage treated is shown in Fig. 23. At BUCK RUN breaker, treating 900 tons per day, wet, with no pure-coal section, 35 men are employed making 25.7 tons per man per 8-hr. day.

Water consumption in anthracite breakers ranges from 0.63 gal. per min. per daily (8-hr.) ton treated in the so-called dry breakers, which use water only for the fine sizes, to 1.54 gal. in the wet breakers in the lower (low-grade) field. (*66 A 422.*) Griffen (*66 A 514*) averages the water consumption at, roughly, 1 gal. per min. per daily ton of production.

Power. An idea of power consumption may be obtained from the description of the Drifton breaker (p. 48).

Bituminous-coal preparation.

From the viewpoint of preparation, bituminous coals, as mined, may be divided into two groups, the first, comprising the bulk of the total production, requiring no cleaning, while of the rest, which requires removal of some impurity, only a part, amounting to between 5 and 10 per cent. of the total bituminous production, requires WASHING (gravity concentration).

The important removable impurities in bituminous coal are shale, clay, pyritic sulphur and bone. When the run-of-mine product is coarse, hand picking is the easiest and cheapest method of removing shale and bone, but when, as is frequently the case, upwards of 50 per cent. of the product delivered at the surface is $-1\frac{1}{2}$-in. slack, separation by picking is uneconomical. With very soft coal the Bradford breaker takes advantage of the relative toughness of the shale to deliver it as oversize separated from the coal and fine shale, which discharge as undersize. Separation of pure coal from free shale and from free pyrite is easy, since the free-settling ratios are about five and twelve respectively, but if there is much bone (sp. gr. from 1.35 to 1.70) the problem becomes more difficult, particularly as regards the finer sizes, and the fact that crushing is rarely carried far enough to free either shale or pyrite with any pretense to completeness makes high elimination of either ash or sulphur unusual. While no general rules can be set down, experience shows that reduction in sulphur content ranges in general between 25 and 40 per cent., rising to 50 per cent. on some coals and even higher in a few exceptional cases. The organic sulphur is practically unaffected by washing, as is shown in Table 25. According to Campbell (*63 A 683*) a reduction of 50 to 60 per cent. in ash content is a fair expectation.

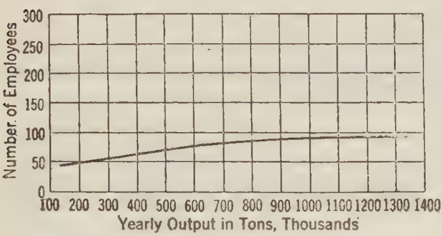

FIG. 23.—Labor in anthracite preparation.

Steam-coal tipple. Much coal is shipped directly as brought out of the mine. Most of the clean-coal mines, however, are provided with at least a simple screening plant (TIPPLE) in which crude separation is made on a screen of from 1- to 3-in. aperture (commonly $1\frac{1}{2}$-in.) between SLACK (undersize) and LUMP (oversize).

Fig. 24 shows a well-arranged tipple for handling steam coal. At the left is a dump-house for receiving run-of-mine coal that is to be shipped as such, a feeder and an elevating conveyor which delivers by way of an adjustable chute to railroad cars. At the right side are another hopper, feeder and conveyor delivering to the screening plant. This plant is flexibly arranged to permit of several dispositions of the coal, *e.g.*, (*1*) delivery to

screen (*a*) with aperture of from ¾-in. to 1½-in., the undersize going to the slack bin for shipment and the oversize to wagons or trucks for domestic consumption; (*2*) delivery to screens (*b*) fitted with, say, 4- to 6-in. screen, and screen (*c*) fitted with 1½- to 3-in. screen, thus producing lump coal on track No. 2, egg size on track No. 3, and slack through the bin onto track No. 4. (*3*) By putting blank sheets into screen (*c*), run-of-mine coal may be delivered onto track No. 2. (*4*) By putting a slack screen on screen (*b*) and delivering directly thereto from the conveyor, fine lump may be delivered on track No. 3 and slack on No. 4. (*5*) Finally, by putting blank plate on screen (*b*) and delivering directly thereto, run-of-mine coal may be delivered to track No. 3. Provision is also made to run slack to storage by means of a conveyor under the slack bin. The screens shown are of the fixed-inclined type (Sec. 5, Art. 4), but may also be either rotary or shaking types, which reduce the required headroom. They are built to allow ready change of plate, in order to attain the flexibility described.

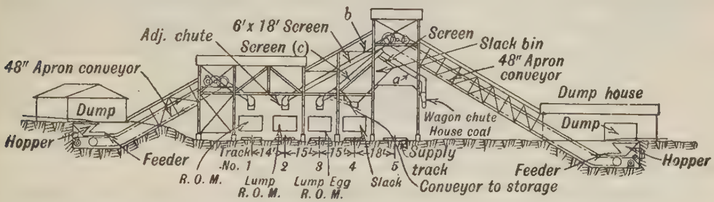

FIG. 24.—Typical steam-coal preparation plant (*after Read, 6 CA 255*).

When a coal requires cleaning, the treatment demanded depends upon the character of the coal. In some coals the removable impurity (FREE ASH) occurs in the coarser sizes and the slack is of better grade than the run-of-mine coal.

Example: At POCAHONTAS COAL CO., Palmer, Wash. (*28 Bul. UW 143*), the +⅜-in. raw coal assays 41 per cent. ash, the −⅜-in. 27.8 per cent., and the total 35.3 per cent.

In a converse case the impurity concentrates in the slack.

Example: At RENTON COAL CO., Renton, Wash. (*ibid.*), the entire coal assayed 18.7 per cent. ash, the + 3-in. size 13.3 per cent., and the −⅜-in. 25.6 per cent.

In another class of coal the impurity is of substantially uniform distribution and two cases arise: (*a*) when the coal is non-salable without cleaning and, (*b*) when cleaning improves the selling price in an amount greater than the cost of the cleaning operation. With a coal such as the latter it may be that the slack will not stand the cost of further treatment while the coarser sizes will. This is frequently the case when the coarse coal is sold for domestic use.

Table 25. Effect of washing on sulphur reduction in an Illinois washery. (*After Fraser & Yancey, 63 A 773*)

Material	Percentages of sulphur			
	Total	Pyritic	Sulphate	Organic
Raw coal..................	1.83	1.04	Trace	0.79
Washed coal, No. 1 size......	1.81	1.05	....	0.76
Washed coal, No. 2 size......	1.56	0.78	....	0.78
Washed coal, No. 3 size......	1.57	0.82	....	0.75
Washed coal, No. 4 size......	1.57	0.81	....	0.76
Washed coal, No. 5 size......	2.33	1.57	....	0.76

NOTE: In another case sulphate sulphur was reduced from 0.11 per cent. to less than 0.01 per cent. by washing.

The greater value of cleaned coal is due to its greater heating value per unit of weight, the lower freight charge per unit of heat, the greater absolute heating value due to the removal of non-combustible heat-consuming material, reduction in clinkering and in the weight of ash to be handled, reduction in the amount of smoke and soot, and reduction in corrosive effect of the gases and soot. When coal is to be used for making metallurgical coke, the requirements of high compressive strength and low-sulphur content in the coke bar high-ash high-sulphur coals although the coals themselves may possess the essential coking characteristic. Frequently washing will remove the objectionable ash and sulphur sufficiently so that the residue is suitable for coking, in which case the value of the coal is considerably enhanced.

Cleaning plants vary in complexity from relatively simple screening and hand-picking tipples, in which the coarse material only is treated, to relatively complicated gravity-concentration plants with close sizing preceding jigs or pneumatic tables. Shaking tables are used in some cases to clean fine sizes. Flotation and granulation are both applicable to cleaning very fine sizes, although both processes are relatively expensive and economically useful, at the present, only in a few special cases.

The flow-sheets for bituminous preparation are simpler than those employed for anthracite, the apparatus is generally fed at a higher rate, and the results, from the standpoint of concentration, are not so good.

The requirements of bituminous users are not, in general, so strict as those of anthracite consumers, and the selling price of bituminous coal will not permit more elaborate cleaning.

Table 26. Trade sizes of bituminous coal (35 Illinois washeries). (*After Lincoln*)

Name of size	Upper limiting screen, inches	Lower limiting screen, inches
Nut.........	2½ to 1¼	1¼ to ¾
Slack.........	2 to ¾	3/16 to 0
No. 1 extra..	3¾ to 3	3 to 2½
No. 1.......	3½ to 1½	2¼ to 1⅜
No. 2 extra..	2¼ to 1¾	1¾ to 1⅜
No. 2.......	2¼ to 1⅜	1½ to ⅞
No. 3.......	1½ to 1	1 to 3/32
No. 4.......	⅞ to ⅝	⅜ to 3/16
No. 5.......	⅜ to ¼	3/16 to 0

Sizing. When bituminous coal is prepared for domestic use, it is graded into a number of sizes as is domestic anthracite, but ordinarily not so many sizes are made and the trade sizes are not so closely standardized. Lincoln (*11 Bul. UI No. 9*) gives the data summarized in Table 26 showing Illinois practice.

Hand-picking plants are used for coals that have the impurity concentrated in the coarse sizes, or when the slack will not stand the cost of washing. Fig. 25 shows the flow-sheet of a relatively small but well-arranged plant. The apron feeder (*g*) and clutch drive on conveyor (*k*) permit individual carloads to be spaced on the picking table and the waste therefrom to be separately collected and weighed and, if desirable, set aside in cars for the loader's inspection.

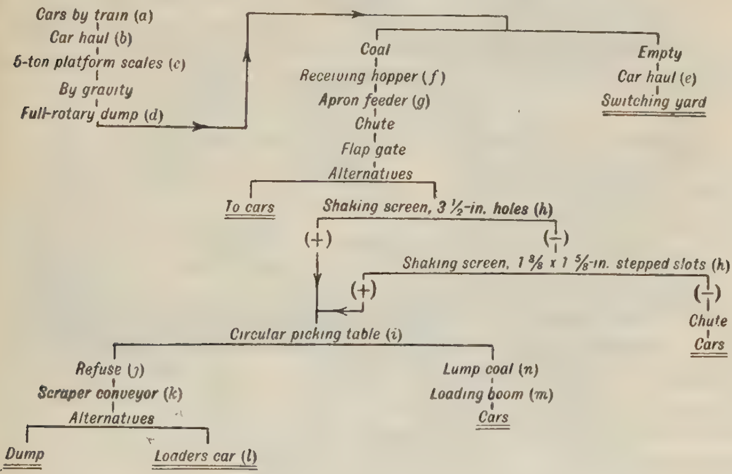
Imperial Coal Corporation, Diamond mine (*19 CA 1111*). Fig. 25.

Location: Johnstown, Pa.
Capacity: 225 tons per hr.

Summary. Screening into two sizes of lump coal for hand picking. Subsequent separate shipment or re-mixing as desired.

Picking and screening plants. Fig. 26 shows plan and elevation of an unusually elaborate plant for screening and picking bituminous coal, the slack being suitable for coking without further treatment other than crushing. The figure is self-explanatory, except that it is to be noted that the nut size

is re-screened in a revolving screen between the nut shaker and the picking table. Maximum CAPACITY of this plant is 750 tons per hr. Loading booms with adjustable finger chutes at the discharge end permit loading of sized products with a minimum of breakage. The flow-sheets (Figs. 27 and 28) show plants similar to a simple anthracite breaker for preparing coal coarser than slack for domestic use, the slack being sold without cleaning.



a, Upwards of 50 cars to a train, electric locomotive. *b*, 12 ft. 8 in. center to center of sprockets. Chain bars, $2\frac{1}{4} \times \frac{5}{8}$-in.; pins, 1-in. steel. Forged-steel hooks, engaging car axle or special plates, are placed at 10-ft. 8-in. intervals. Speed, 35 ft. per min. Head shaft, $3\frac{15}{16}$ in.; tail shaft, $2\frac{7}{16}$ in. Average carload is 4200 lb. and haul will move the entire train. 10-hp. motor drives through belt, cut-steel spur gears and roller chain. 14-in. friction clutch on drive pulley. 0.6-per cent. adverse grade. *c*, Quick-weighing type, with reading dial. *d*, Push-button control. Locking, turning and discharging empty cars, automatic. *e*, Capacity is 50 empty cars on adverse 0.6-per cent. grade. Empties weigh 1700 lb. each; 60 ft. per min.; 44 ft. center to center. Hooks at 5-ft. 4-in. centers. Chain and shafts as in (*b*). Rachet-and-pawl safety device on head pulley. *f*, Air-controlled flap gate permits discharge through either of two feeders. *g*, 17 ft. long, 6 ft. 6 in. wide, $\frac{1}{4}$-in. double-beaded pans. *h*, 6 ft. wide × 16 ft. long. $\frac{3}{16}$-in. side plates and $\frac{1}{4}$-in. bottom plates. *i*, 10 ft. inside diameter, 20 ft. outside diameter, divided by circular partition. Lump on outer deck and coal on inner. 50 ft. per min. mean speed. $\frac{1}{4}$-in. removable cover plate. 25-hp. motor for two tables. *j*, Picked. *k*, Conveyor chutes suspended from 1.5-ton scale so that waste from any car can be read. *l*, To be held for loader's inspection. *m*, Jointed 36-in. pan conveyor, outer 21.5 ft. hinged, and raised and lowered by 2-ton electric hoist. Belt speed, 75 ft. per min. Raising speed, 17 ft. per min. *n*, Sizes may be loaded separately.

FIG. 25.—Imperial Coal Corporation.

Economy Domestic Coal Co. (*19 CA 1151*). Fig 27.

Location: Riddlesburg, Pa.
Feed: Hard, semi-bituminous coal.

O'Gara Coal Co. (*25 CA 557*). Fig. 28.

Location: Harrisburg, Ill.
Capacity: 3000 tons per 8 hr.

Washing is employed when the slack requires cleaning. In some cases the coarse sizes are hand picked and the slack washed, in other cases both

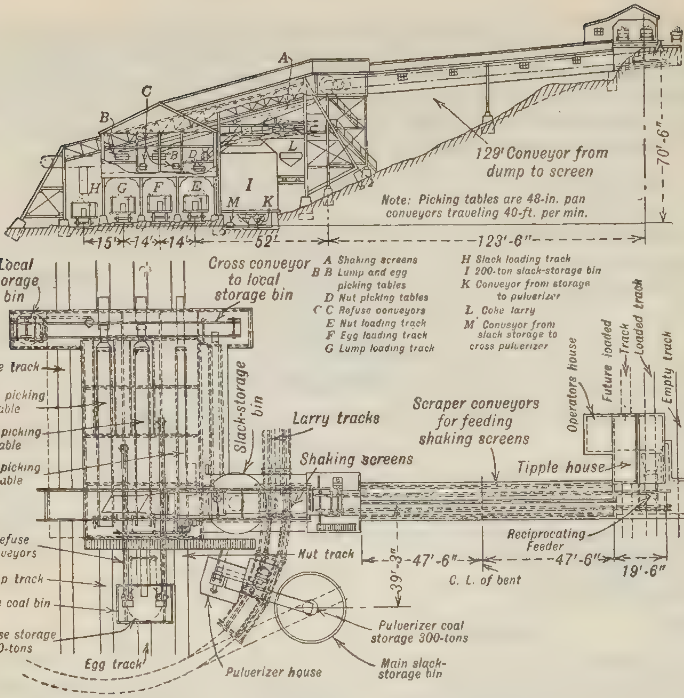


FIG. 26.—Screening and picking plant for preparing sized bituminous coal (*after Read, 6 CA 255*).

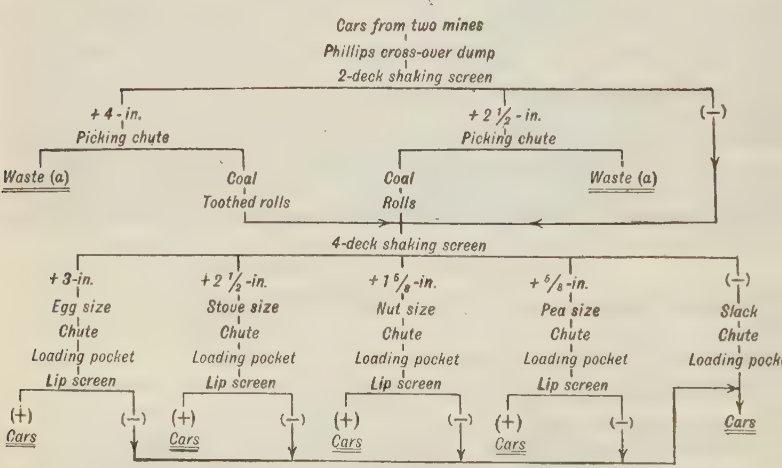
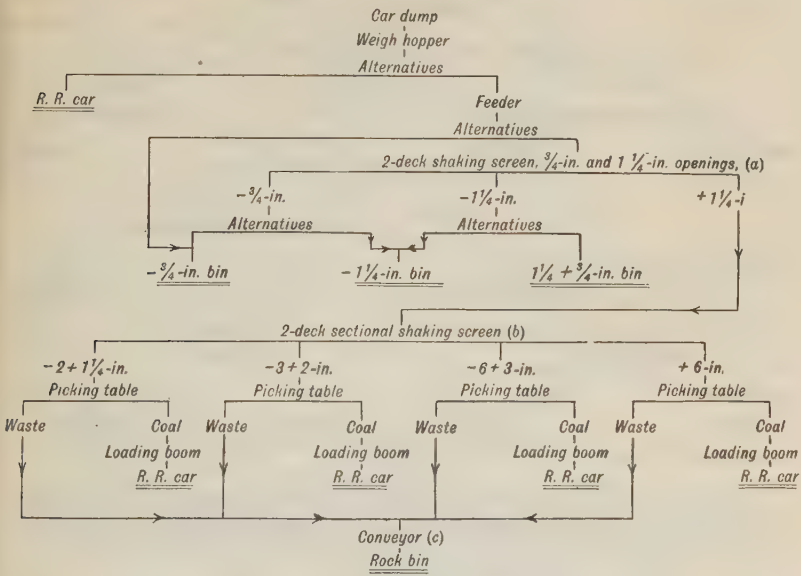


a. Picked.

FIG. 27.—Economy Domestic Coal Co.

coarse and fine sizes are washed, either together or separately, and in yet other cases the coarse material is crushed and the whole coal washed at −3-in. size or smaller.



a, Screening surface on each deck 29 ft. long. *b*, Upper deck has 18 ft. of 3-in. and 8 ft. of 6-in. screen followed by a blank section; lower deck has 18 ft. of 2-in. screen.

Fig. 28.—O'Gara Coal Co.

The devices used for washing range from crude trough sluices to fairly elaborate jigs. Recently, also, shaking tables have been used to some extent and several plants have been built that employ pneumatic concentration.

Washeries are frequently named from the particular type of concentrating device used, *e.g.*, a Stewart washery or a Luhrig washery, indicating that Stewart or Luhrig jigs are employed.

Trough washeries are the simplest and crudest form of washing plant. These plants have been used rather extensively at English and Scottish mines. Typical flow-sheet is given in Fig. 29. For data concerning size and performance of coal-washing troughs, see Sec. 8, Art. 12.

Elliott washery. See Sec. 8, Art. 12.

Rheolaveur washery is a modern development of the trough washery. (See Sec. 8, Art. 5, for description of the Rheolaveur apparatus.) Fig. 30 shows the arrangement of a typical plant. This type of washery has made considerable advance in England and has given promising

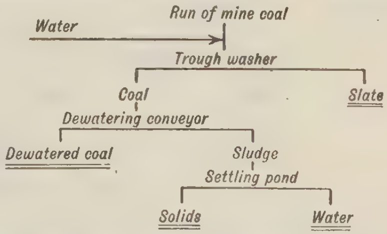


Fig. 29.—Flow-sheet of a trough washery.

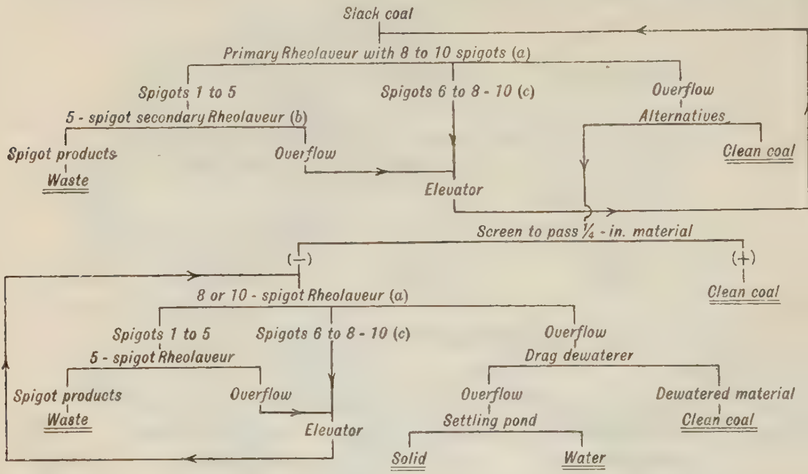
results in the United States. The cost at a British washery (1923) treating 100 tons per hr. was $0.055 per ton (*67 IME 501*).



a, Run with weak rising currents. *b*, Run with strong rising currents. *c*, If a second-grade coal is desired spigot products 8 to 10, *e.g.*, may be diverted directly to this supply or sent to another, secondary Rheolaveur which will remove more impurity and insure a relatively constant grade.

Fig. 30.—Rheolaveur washery.

Tube washeries employ some form of tubular classifier as the separating device. They treat relatively fine, sized feeds. Fig. 31 shows a typical flow-sheet. (See also Draper washer, Sec. 8, Art. 5.)

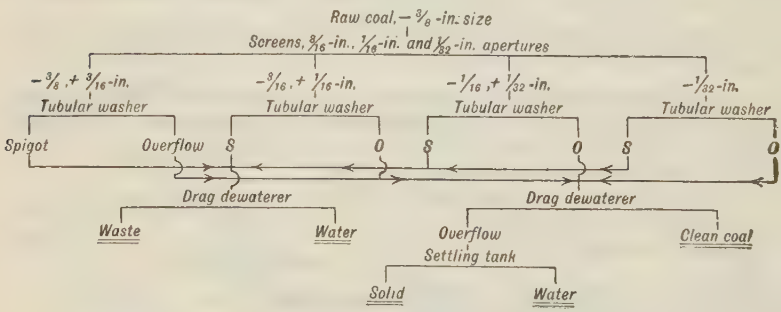


Fig. 31.—Tube washery.

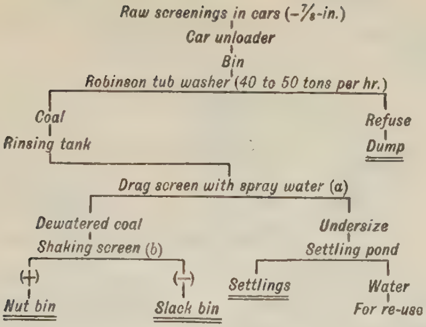
Tank washeries are those that employ tanks like the Robinson, Howe, Chance or Conklin washers as the principal separating machines. Figs. 32 and 33 show a typical Robinson washery.



a, 4 × 20-ft., 3/32-in. round holes; slope, 40°; 100 ft. per min. *b*, Parrish type, supported, 4 × 10-ft., 15/16-in. round holes; slope, 4°; 132 @ 6-in. strokes per min. Feed, 34 tons per hr., −7/8-in. slot.

Fig. 32.—Robinson-tub washery at B. F. Berry Coal Co., Granville, Ill. (*after Lincoln*).

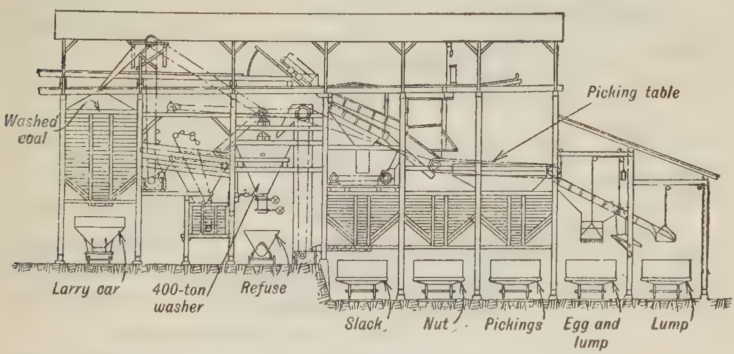


Fig. 33.—Robinson washery.

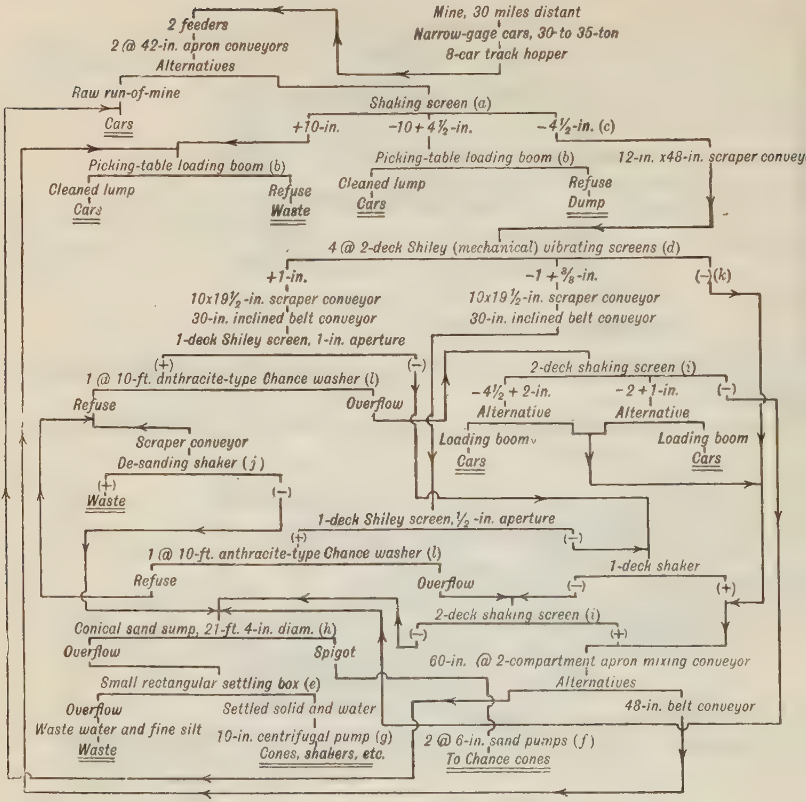
East Broadtop Railroad and Coal Co. (*PP 1535-F A.*) Fig. 34.

Location: Mt. Union, Pa.
Capacity: 500 tons per hr.
Coal: Low-volatile, slow-coking; ash of high-fushion temperature.
Power: See Table 27
Labor: 24 men per shift.
Analyses:

	Ash, per cent.	S, per cent.
Washed coal, −4½ +1-in.	7.5	1.10
Washed coal, −1 +3/8-in.	7.1	1.22
Raw coal, −3/8-in.	7.9	1.10
Shipped mixture, −1-in.	7.4	1.20

Total refuse = 4 to 5 per cent. of feed, indicating about 2½ per cent. ash reduction.
Estimated cost of plant, based on complete new tipple, $125,000 to $150,000.
Cost of operation: $0.0964 per ton of coal shipped, based on 24 days per month at 400 tons per day and average labor cost $0.80 per hr.



a, 6 ft. wide × 25 ft. long, 4½-in. rd. holes followed by bars with 10-in. spaces. *b*, Apron-conveyor type. *c*, Exceeds 400 tons per hr. *d*, Slope about 30 per cent., 1200 to 1500 vibrations per min. 1¼- to 1½-in. screens on upper deck and ½- to ⅝-in. screens on lower deck. *e*, Acting as feed box for centrifugal pump. *f*, Actual lift about 14 ft. Capacity about 1000 gal. per min. 25-hp. motors. *g*, 2500 gal. per min. capacity, 50-hp. motor. *h*, 200 to 300 gal. per min. of make-up water added here. *i*, Top deck 5 × 26 ft.; bottom, 5 × 23 ft. with a 4 × 17-ft. shaking-chute extension. Upper deck carries a 5 × 9-ft. de-sanding section with 3/32-in. round-hole bronze plate. Upper and lower decks driven by separate eccentrics set 180° apart and both screens driven from a common shaft with 48-in. flywheel to partially overcome lack of balance between upper and lower decks. 160 r.p.m. *j*, 3-ft. 6-in. × 11-ft. 6-in. top deck (3/32-in. screen) and 4-ft. × 11-ft. 6-in. bottom deck with blank plate, 160 r.p.m. *k*, About 70 tons per hr. *l*, Classifier columns are 22-in. diameter to permit handling large sizes. Hydraulic thrust valves, manually operated are used for trapping out slate. Sand loss was between 1.0 and 1.5 lb. per ton of coal washed. Sand cost was $1.59 per ton f. o. b. plant. Specific gravity in coarse cone, 1.55; fine cone, 1.45. Performance of coarse cone:

	Ash, per cent.	S, per cent.	B.t.u.
Raw coal, −4½ +1-in.	17.75	1.58	13,680
Washed coal	7.42	1.10	14,580
Refuse (including that from fine cone)	58.60	3.59	5,602

Density is tested four times per day.

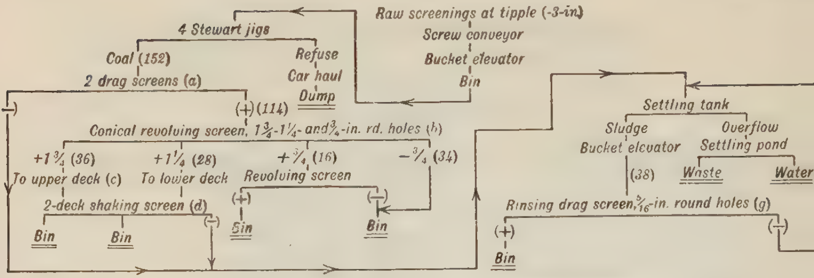
1.09 tons per hp.-hr. (installed) for entire plant; 1.37 tons per hp.-hr. (installed) for sizing and washing.

Summary. Feed divided at $4\frac{1}{2}$-in., oversize hand picked, fines screened from undersize and shipped without treatment, $-4\frac{1}{2} + 1$-in. washed by Chance process in two sizes.

Jig washeries

In these plants the principal separating machine is a jig. Two general types of flow-sheet have developed, depending partly on the character of the coal being treated and partly on whether a pan jig or a fixed-sieve jig is employed. With coals that are easy to clean and, in general, in pan-jig washeries, unsized slack as coarse as 3-in. maximum is fed directly to the jigs and any sizing desired is performed on the washed coal. Many plants treating difficult coals size closely before jigging and for treating the sized products use piston jigs. The Stewart washery (Fig. 35) is typical of the use of pan jigs. The Tennessee Coal, Iron and Railroad Co. (Fig. 36) shows the use of a piston jig in similar service, but taking a much finer feed. The plant at Woodward Iron Co. (Fig. 37) is similar to the preceding but uses a second piston jig to re-treat hutch product and crushed tailing from the first. At Republic Iron and Steel Co. (Fig. 38) shaking tables are used instead of the second jig for treating crushed bone from the primary jig. The Luhrig washery (Fig. 39) shows a plant for treating a difficult coal, with close sizing before jigging.

Chicago and Carterville Coal Co., Herrin, Ill. (*11 Bul. UI No. 9*). Fig. 35.

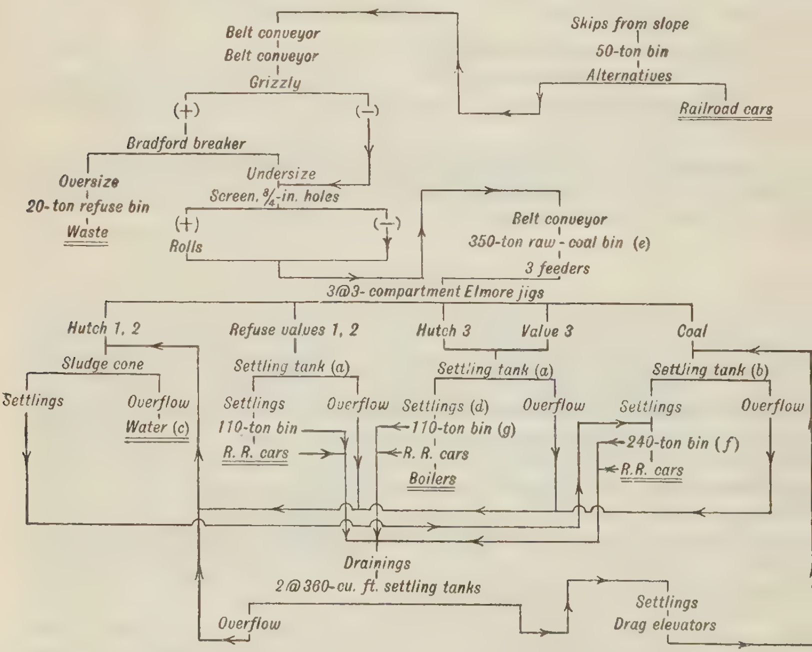


( ) Numbers in parenthesis = tons per hr. *a,* 3 × 28 ft.; lower, 7 ft. with 7/16-in. round holes; upper, 21 ft. with 3/8-in. round holes; slope, 16°; drag speed, 120 ft. per min.; feed, 76 tons per hr. each; 25 per cent. passes through the screen. *b,* Triple-jacketed, compound; inner jacket, 4 and 7½ × 17 ft.; intermediate jacket, 6½ and 10 × 16 ft.; outer jacket, 8 and 12 × 15 ft.; 12 r.p.m. Tons feed per sq. ft. per 24 hr. per mm. aperture: on coarse screen, 0.22; on intermediate screen, 0.14; on fine screen, 0.12. *c,* 3 × 10 ft., 1 1/16-in. round holes, 15° slope. *d,* 130 strokes per min. *g,* 3½ × 12 ft., set level; drag speed, 90 ft. per min.

FIG. 35.—Stewart washery at C. and C. Coal Co.

Tennessee Coal, Iron and Railroad Co. *(71 A 1100).* Fig. 36.

Location: Bayview, Ala. *Capacity:* 100 tons per hr.



a, 900 cu. ft. *b,* 10,600 cu. ft. *c,* 8.7 lb. of solid per 1000 tons of raw coal. *d,* 6.5 per cent. of total raw coal. *e,* 9 per cent. + ¾ in. (*j*). *f,* 19 per cent. + ½ in. (*j*). *g,* 20 per cent. + ¼ in. (*j*). *h,* 14 per cent. + ⅛ in. *i,* 42 per cent. – ⅛ in. *j,* These results are extremely variable.

FIG. 36.—Tennessee Coal, Iron and R.R. Co.

	Weight, per cent.	Proximate analyses			
		Volatile, per cent.	Fixed carbon, per cent.	Ash, per cent.	S, per cent.
Raw coal	100.00	26.42	61.14	12.44	1.76
Washed coal, −1.37 sp. gr.	82.05	28.18	67.06	4.76	1.30

Water circulated, 600 gal. per ton of coal washed. Water lost, 27 gal. per ton of coal washed.

Power: 1.24 kw.-hr. per ton of washed coal.

Summary. Crushing to −¾-in. in Bradford breaker and rolls. Jigging unsized feed. Recovery of fine coal by settling in elevated cone.

Woodward Iron Co. (*71 A 1094*). Fig. 37.

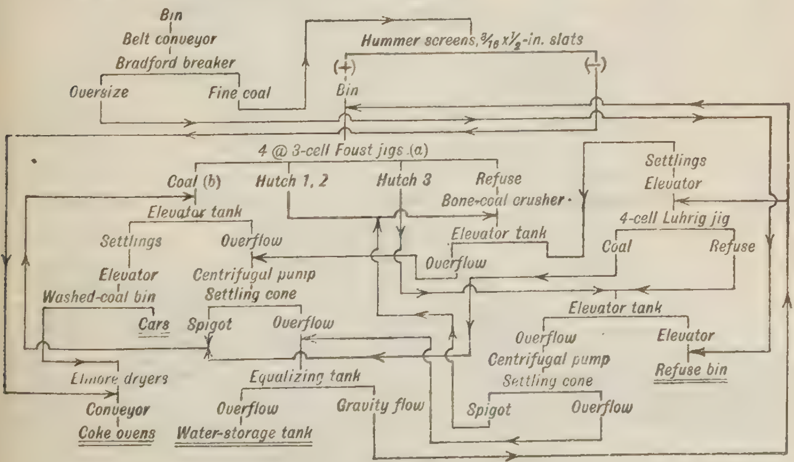
Location: Woodward, Ala.

Assays:

	Weight, per cent.			
	Volatile	Fixed carbon	Ash	Float (−1.37)
Raw coal	26.77	63.52	9.91	.. ..
Fine coal (−3⁄16-in.)	28.03	66.43	5.54	......
Washed coal from primary jigs	.....	.....	5.52	......
Re-washed coal from secondary jigs	.....	.....	9.46	......
Average washed coal	27.95	66.05	6.00	......
Refuse	.....	.....	....	3.21 (*a*)

(*a*) Contained 6.58 per cent. ash.

Water in circulation, 950 gal. per ton of coal washed. Water added, 41 gal. per ton of coal washed.



a, 11.89 per cent. ash. *b*, 5.52 per cent. ash.

Fig. 37.—Woodward Iron Co.

Summary. Screening to separate fine low-ash coal from run-of-mine. Bradford breaker to crush oversize and eliminate coarse refuse. Crushed coal jigged, primary-jig refuse re-crushed and re-jigged together with primary-jig hutch products. Sizing test of jigged coal follows: +0.75-in., 5.9 per cent.; +0.52-in., 2.4 per cent.; +0.26-in., 16.2 per cent.; +0.09-in., 47.4 per cent.; −0.09-in.; 28.1 per cent.

Republic Iron and Steel Co. (*71 A 1096; 19 CA 807*). Fig. 38.

Location: Risco, Ala. *Feed:* Coking coal. *Capacity:* 250 tons per hr.

Assays:

	Weight, per cent.			
	Volatile matter	Fixed carbon	Ash	Sulphur
Raw coal	27.75	55.50	16.75	0.90
Washed coal	28.50	62.25	9.25	0.80

Refuse is 8.5 to 9.5 per cent. by weight. Coal of less than 1.40 sp. gr. in refuse amounts to 1.4 per cent. of such coal fed to the washer.

Water: Consumption is about 25 gal. per ton of coal washed when draining conveyor is not working and coal is loaded out with 10 per cent. moisture. When conveyor is working, coal is loaded out at about 8 per cent. moisture, which is substantially the moisture content of the raw coal, and water loss is very low.

Summary. Crushing through 1-in. round hole in two steps, jigging unsized feed, and recovering fine coal from circulating water in Dorr thickener. The contemplated flow-sheet will separate raw coal at $^3/_{16}$ in. and table the undersize, if necessary, sending oversize only to the jigs.

Table 28. Sink-and-float test on raw coal. Republic Iron and Steel Co., Risco washery. (*After Geismer*)

Sp. gr.	Weight, per cent.	Ash content of grade, per cent.
−1.35	78.7	7.28
1.35–1.40	4.7	14.19
1.40–1.45	4.3	18.24
1.45–1.50	2.4	22.13
1.50–1.55	1.2	28.51
1.55–1.75	1.5	35.85
+1.75	7.2	72.14

Table 29. Sizing-assay (sink-and-float) test of raw coal, Republic Iron and Steel Co., Risco washery. (*After Geismer*)

Size	Per cent.	Per cent. float at				Per cent. sink at 1.75 specific gravity
		1.35 specific gravity	1.35–1.45 specific gravity	1.45–1.55 specific gravity	1.55–1.75 specific gravity

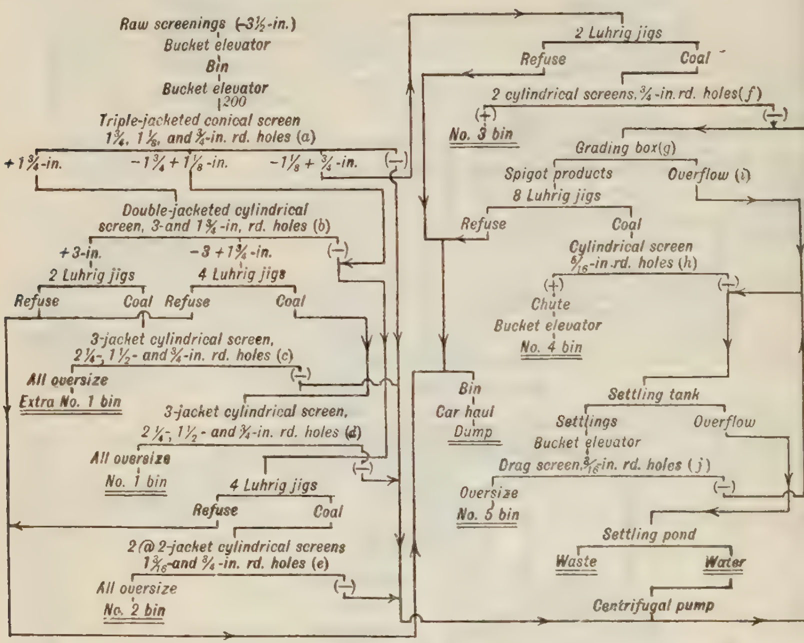
a, When it is desired to inspect a carload. *b*, 1-in. and 2½-in. apertures. *c*, To be used when fines do not require washing and, after the addition of shaking tables, as contemplated, to separate shaking-table feed. *d*, At present. *e*, Proposed. *f*, −60-mesh. *g*, 50 per cent. solids. *h*, Capacity, 70 tons per hr. each. Circulating water, 1300 gal. per min. each jig. *i*, For sink-and-float test, see Table 28; for sizing-assay test (sink-and-float) see Table 29. *j*, With 4 to 6 per cent. solids in the feed the overflow carried 0.15 per cent. and the spigot product about 50 per cent. solids.

Fig. 38.—Republic Iron and Steel Co.

Taylor Coal Co., Carterville, Ill. (LUHRIG WASHERY) is diagrammed in Fig. 39 (*11 Bul. UI No. 9*). It differs fundamentally from the Stewart and other pan-jig washeries in that the feed to the jigs is carefully prepared by screen and hydraulic sizing. The result is a more complicated flow-sheet and a more expensive installation.



Feed rate, 200 tons per hr. *a*, Inside jacket, 5½ × 10 × 16 ft.; intermediate, 7¾ × 12¼ × 15 ft.; outside, 10 × 14½ × 14 ft. Axis level, 8 r.p.m. *b*, Inner jacket, 2½ × 5½ ft.; outer, 3½ × 5 ft. Slope, 4½°. 18 r.p.m. *c*, Inside jacket, 2½ × 7 ft.; intermediate, 3½ × 6 ft.; outside, 4½ × 5 ft. Slope, 3½°. 24 r.p.m. *d*, Inside jacket, 3½ × 7 ft.; intermediate, 4½ × 6 ft.; outside, 5½ × 5 ft. Slope, 3½°. 24 r.p.m. *e*, Each, 2¼ × 7 and 3⅙ × 6 ft. Slope, 3½°. 24 r.p.m. *f*, Each, 3⅙ × 7 ft. Slope, 3½°. 24 r.p.m. *g*, Horizontal-current multiple-spigot classifier. *h*, 5 × 8 ft. Slope, 1°. 12 r.p.m. *i*, Not shown by Lincoln. *j*, 4 × 16 ft. Level. 40 ft. per min.

FIG. 39.—Luhrig washery (*after Lincoln*).

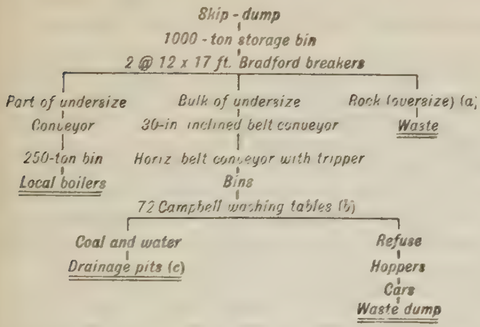
Bumping-table washery is illustrated by Fig. 40. (For description of bumping tables for coal see Campbell bumping table, Sec. 10, Art. 13.)

Cambria Steel Co., Rosedale plant (*23 CA 285*). Fig. 40.

Location: Johnstown, Pa.
Capacity: 4000 gross tons per 10 hr.

Air-cleaning plants is the name given to plants using pneumatic separators as the principal separating machines. Pneumatic machines require closely-sized granular feeds, not too coarse, hence screens are a large part of the plant requirement; all of the feed should be crushed to pass a 1-in. or 1.5-in. screen, or some other method should be provided for handling the

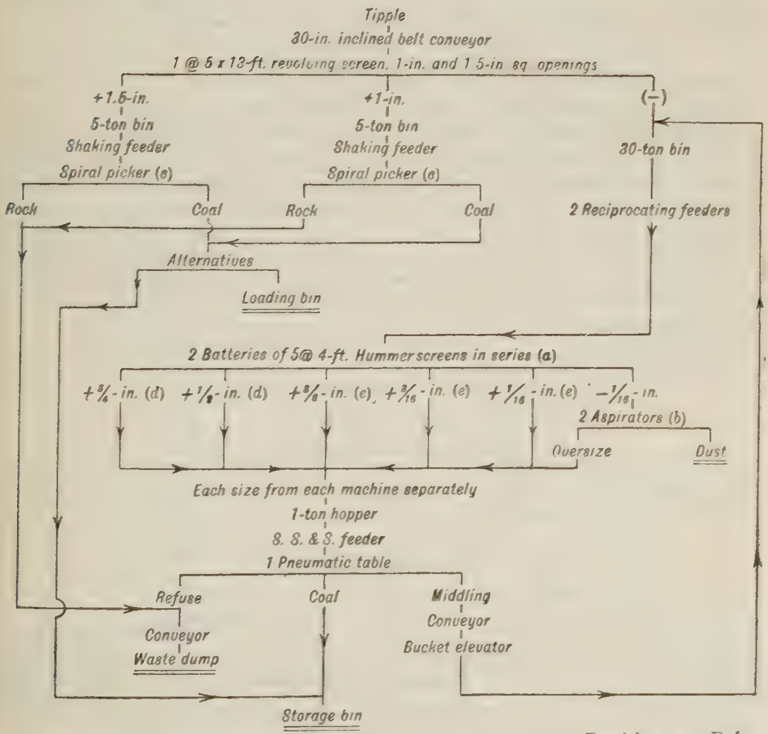
coarser material; and provision must be made for dust separation, collection and disposal. Fig. 41 shows a typical air-cleaning plant. See also Sec. 14, Art. 2.



a, Cobble loss of 1 per cent. *b*, For performance see Sec. 10, Table 35. *c*, 10 shallow rectangular concrete pits, capacity of each 1500 tons. Drainage period ordinarily four days. Drained coal contains 6 to 8 per cent. moisture. Pits are served by two unloading cranes with a chain-bucket digging boom delivering to a 36-in. belt conveyor serving all pits.

FIG. 40.—Cambria Steel Co. coal washery.

St. Louis, Rocky Mountain and Pacific Co., Brilliant mine (*23 CA 791*). Fig. 41.



a, Spaced 8 ft. 3 in. center to center. *b*, See Sec. 14, Art. 2. *c*, Parrish type. Refuse contains about 25 per cent. coal but this is as good as done by the ¾-in. (coarsest) pneumatic table. *d*, Square mesh. *e*, Ton-cap.

FIG. 41.—St. Louis, Rocky Mountain and Pacific Co.

Location: Raton, N. M.
Capacity: 800 tons per 8 hr.
Labor: One foreman and three laborers.
Performance: See Sec. 14, Table 3.
Cost: Young (*loc. cit.*) says that the first cost of a dry plant such as this is about 20 per cent. more than a wet-process plant; that the cost of power is a little higher and of labor about the same.

Flotation is not, at present (1926), practiced in any domestic washeries. There are a few plants in Great Britain. A flow-sheet of one of these is shown in Fig. 42 (*67 IME 510*). Ordinarily the feed is − 0.1-in. material, but this flow-sheet shows an application to a coarser feed.

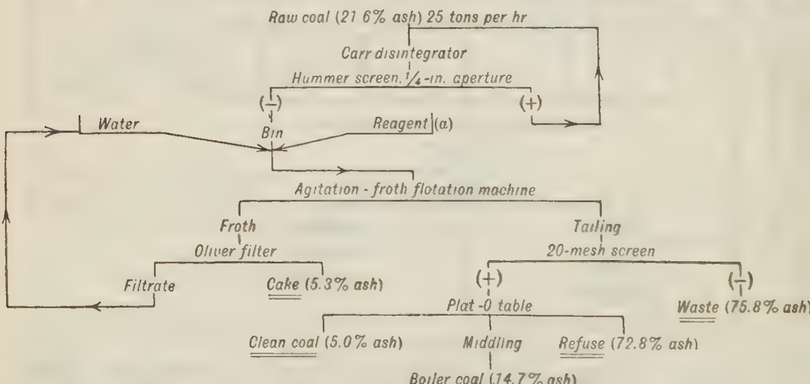
Crushing in coal preparation is never carried to the extent required to free a percentage of impurity equivalent to the percentage of metal freed in metal concentration. As a result, coal washing must be looked upon as a process of concentrating rich middling from poor middling and be judged accordingly.

In a test by Messmore, quoted by McMillan and Bird (*28 Bul. UW 198*), a sample of raw Washington coal, sized between ¾- and ⅜-in., was separated into various specific-gravity fractions, each was crushed to pass 60-mesh and again separated by a sink-and-float test. The lightest fraction of the original lot (− 1.35 sp. gr.), which analyzed 5.4 per cent. ash when crushed, yielded a small amount of material containing 66.7 per cent. ash and the heaviest fraction (+ 1.70 sp. gr.), which analyzed 69.7 per cent. ash yielded a small amount of material containing 5.5 per cent. ash and 3.3 per cent. with less than 9 per cent. The fraction 1.40 to 1.45 sp. gr., which contained 18 per cent. ash, yielded 62.3 per cent. containing 9.8 per cent. ash and 37.7 per cent. assaying 31.6 per cent.

Water required in bituminous-coal washeries varies with the type of washer. According to Campbell (*63 A 683*) the average water consumption of two-compartment jigs is three to four tons of water per ton of coal washed. O'Toole (*20 CA 3*) sets the water consumption in jig plants at 6 tons per ton washed. Shaking tables require a total of one to two tons of water per ton of feed, of which 75 per cent. is feed water. The water lost by leakage, evaporation and moisture in the coal and waste is about 50 to 60 gal. per ton of feed.

Moisture in washed coal is an important disadvantage of washing. O'Toole (*20 CA 3*) points out that when ash reduction is slight and the washed coal is to be shipped long distances the freight on moisture added in washing may counterbalance the enhanced value due to ash reduction.

He cites as an example a washed coal shipped from Indiana to Illinois that ranged



***a*, 0.77 lb. cresylic acid and 0.37 lb. of gas oil per ton.**

FIG. 42.—Flow-sheet for treatment of − ¼-in. slack coal by froth flotation at a British colliery (*after Sinnatt and Mitton*).

between 12.7 and 18.5 per cent. moisture as against a range in moisture content of unwashed Illinois coal received at the same plant of 6.5 to 11 per cent. and an average in Pocahontas coal of 2.3 per cent. High moisture content adds greatly to the cost of unloading in freezing weather. When coal is to be pulverized, it must first be dried, and here again washing is disadvantageous.

Breakage is by no means so important a consideration in bituminous-coal preparation as in anthracite, unless domestic sizes are being made and sold at a considerable advance over screenings. Drakeley (*54 IME 449*) states that the experience in English washeries is that there is much breakage in Robinson washers, less in trough washers and least in jigs. He quotes an experiment from *53 Black Diamond 165* to the effect that the breakage caused by dropping coal 10 to 15 ft. onto an iron plate was three to four times as great as when the coal dropped onto a wooden board.

Performance of bituminous-coal washeries. Tables 30 to 34 (*Lincoln, 11 Bul. UI No. 9*) indicate that so far as Illinois coals are concerned, the lump

a Results in parentheses were not obtained by Lincoln but are from sources believed by him to be reliable. *b* "Bone." *c* Hand picked.

product screened out of the run-of-mine coal and picked contains just about the same amount of ash and less sulphur than the unmined coal in the face and that the raw-coal screenings contain about twice as much ash and somewhat more sulphur than the unmined coal. Washing the screenings cuts the ash content just about in half, bringing it back to that of the unmined coal, and cuts off about 25 per cent. from the sulphur content, lowering it to slightly below that of unmined coal. The calorific values, of course, follow the ash content. Here then, except for the slight sulphur reduction, washing merely serves to remove the waste introduced in mining, but, since washing is a cheap process and mining expensive, it is more economical to remove mined waste in the washer than to mine so as to exclude the waste. Table 33 gives an idea of the size distribution of the washed coal. Table 34 compares average performances of the various types of washeries treating Illinois coals.

Cost of washing per ton of raw coal washed in Illinois in 1912 (*11 Bul. UI No. 9*) including power, labor, supplies, repairs and renewals averaged $0.105 for 15 washeries with a range from $0.03 to $0.18. Lincoln notes in giving these costs that where mine and washery are operated from the some power plant the power charge to the washery is frequently too low or omitted entirely, with the result that the above average is probably low. Average cost of Illinois washeries per hourly ton of rated capacity was $351 with a range of from $130 to $583. Average for 7 washeries with hourly capacities of 100 tons and under was $448, while that for 8 washeries of more than 100 tons hourly capacity was $266. Three Luhrig-jig washeries averaged $393, six Stewart-jig washeries $341, and two Robinson-tub washeries $322.

13. Cobalt, Co.

Properties. Metal; pinkish white, lustrous, malleable, ductile, very tenacious, readily polished, markedly magnetic. (See also Table 1) AT. WGT., 58.9. In compact form practically unchanged in air; in powder may ignite spontaneously. Dissolves slowly in most acids, readily in nitric, forming corresponding salts. Cobalt ion is both bi-valent and tri-valent, base- and acid-forming. Cobalt alloys readily with other metals, notably nickel and iron.

Uses. The principal use is in the ceramic and enamel industries, to impart a deep, intense blue. For this purpose the oxide is used. Alloys of cobalt with iron are used in making magnet steels and "stainless" steel, and an alloy with chromium and tungsten, STELLITE, is a substitute for high-speed tool-steel, although at present rather expensive. Cobalt salts are used and are very effective as catalyzers in drying oils and varnishes (*16 IEC 957; Circ. 186, Paint Mfr's Assoc. of U. S., 1*).

Ores. The economic minerals are: cobaltite, erythrite, smaltite and linnaeite, usually associated with nickel and iron. The main source of supply is Sudbury, Ontario, where the ore is a nickeliferous pyrrhotite which occurs in enormous masses at the contact of quartzite and diorite. There is also an important deposit in the Belgian-African copper field.

Production. To date the Canadian production only is of importance. This has ranged from a maximum of roughly 1,200,000 lb. of cobalt oxide (70 per cent. Co) and 475,000 lb. of cobalt metal in 1918 through a minimum of 217,000 lb. of oxide and 22,000 lb. of metal in 1921 to 750,000 lb. of metal in the form of oxide, metal, salts and treatment residues in 1924 (*33 MI 165*).

Selling. Canadian ores and treatment products containing from 5 to about 12 per cent. Co are sold to refiners in the United States on complicated schedules (see *Spurr and Wormser*), which, of course, depend on the prices obtainable for the metal and oxide. These prices have varied from $1.50 to $1.65 per lb. for the oxide and $2.25 to $2.50 for the metal in 1918 through

\$2.00 to \$4.00 for oxide and \$3.00 to \$6.00 for metal in 1920 and 1921 back to \$2.10 to \$2.25 and \$2.50 to \$3.25 for oxide and metal respectively in 1924. The oxide quoted is the black oxide containing 70 to 71 per cent. Co and not over 1 per cent. Ni. The metal is about 97 per cent. Co with Ni and C the principal impurities.

Treatment. Cobalt minerals are concentrated, usually with the silver and other metallic sulphides present in the ore, and the concentrate, either before or after cyanidation, is roasted to drive off sulphur and arsenic; the resulting oxides are then dissolved and separated by fractional precipitation of their salts.

14. Copper, Cu.

Properties. Metal: red, lustrous, soft, highly ductile, markedly low electrical resistivity (See also Table 1.) At. wt., 63.6. Unchanged by dry air at ordinary temperature. In moist air, after considerable time, a very thin layer of oxidation compounds forms which protects the body of the metal. At red heat it combines rather rapidly with oxygen. Dilute hydrochloric and sulphuric acids do not attack copper in the absence of oxidizing agents, but reaction takes place slowly in the presence of air. Hot concentrated sulphuric acid attacks it. Nitric acid in any dilution dissolves it, the activity of the reaction increasing with the concentration of acid. Copper ion is uni- and bi-valent, usually base-forming, but in some compounds forming part of a complex anion. Copper alloys freely with many other metals.

Uses of copper are multitudinous. It is, under most circumstances, the most economical conductor of electricity and hence is used widely for electrical machinery and transmission; its resistance to corrosion by air, water, and weak acids makes it valuable for certain parts of structures such as roofing, gutters, window screens, ship bottoms, for cooking utensils, and for pipes and containers in chemical and manufacturing plants. It is the main constituent of many alloys, notably brass and bronze which, like copper, can be drawn, and unlike copper, can be successfully cast and, being harder than copper, can be worked in a lathe. Copper chemicals such as the sulphate, carbonate, cyanide, etc., find wide use in the arts, and as germicides and fungicides.

Ores. The economic minerals are atacamite, azurite, bornite, bournonite, brochantite, chalcanthite, chalcocite, chalcopyrite, chrysocolla, native copper, covellite, enargite, cuprite, malachite, melaconite (tenorite) and tetrahedrite. Copper is found in practically every type of ore deposit and associated, in one place or another, with practically every metallic and rock-forming mineral. The largest and best-known deposits are the sulphide-vein deposits of Montana, the native-copper deposits of the Lake Superior region, and the "oxidized" and "porphyry" deposits of the southwestern United States. At Butte, Montana, the ore-bearing veins occur in granite, the chief copper minerals are chalcocite, enargite, bornite, and chalcopyrite, and the principal associated vein minerals are quartz and pyrite; minor minerals are covellite, tetrahedrite, tennantite, sphalerite, argentite, gold, and minerals containing bismuth, tellurium, selenium, nickel and manganese. In the Lake Superior region the native copper, associated with native silver, occurs as part of the cementing matter in a conglomerate, as a cavity filling in lava beds, and in veins cutting both igneous and sedimentary rocks. The usual gangue minerals are calcite and zeolites. The "oxidized" deposits of the southwest carry large amounts of the oxidized copper minerals malachite, azurite, and cuprite, and directly below or closely associated with these, bonanzas of massive secondary chalcocite. Both classes of minerals are derived from the primary copper sulphides, largely chalcopyrite and cupriferous pyrite, which are found unaltered in greater depths. The deposits occur in limestone or at limestone-porphyry contacts. There are also numerous granitic intrusions associated with the ore-bodies which have caused the formation of characteristic contact minerals. These deposits are char-

[illegible] of the Bisbee and Clifton districts. The deposits of the Jerome district [illegible]. [illegible] occur in fissures and as impregnations in the country rock near intruded granite dikes. The "porphyry coppers" are mineralized zones in granite porphyries and schists. The principal copper mineral is chalcocite, which occurs as grains and veinlets in the country rock. Pyrite, chalcopyrite, and magnetite are the principal metallic associates; quartz and the rock-forming silicates form the non-metallic gangue. An enormous disseminated deposit containing soluble sulphates of copper occurs at Chuquicamata, Chile, and in the Katanga province of Belgian Congo are a number of high-grade deposits in which the principal copper mineral is malachite.

Production statistics are shown in Tables 35 and 36.

a Mineral Industry.

Selling. Electrolytic copper, 99.90 to 99.95 per cent. combined copper and silver; Lake copper, the melted and furnace-refined product from the Lake Superior mills, of the same purity; arsenical Lake, analyzing upwards of 99.88 per cent. copper plus silver plus arsenic; and re-melted scrap are the principal grades in which copper is sold in the United States. Some small amounts of high-grade blister copper and cathode copper are also dealt in. The metal is sold in the form of wire bars, ingots and ingot bars, and slabs and cakes. Selling is largely in the hands of a few agencies in New York City. (For details of selling methods see *Spurr and Wormser* and the bibliography therein.) Average prices in recent years are given in Table 37.

Table 37. Average prices of electrolytic copper at New York. (*Eng. and Min. Jour.*)

Year	Cents per pound
1913	15.27
1919	18.69
1920	17.46
1921	12.50
1922	13.38
1923	14.42
1924	13.02
1925	14.04

Most copper, as it leaves the mills, is in the form of a sulphide concentrate and the contained metal is subject to charges for freight, smelting, refining and selling. For typical schedules, see Art. 33.

Treatment of copper ores depends upon the nature of the ore itself. There are three general methods of treatment, viz.: *(1)* Direct smelting for high-grade ores, containing upwards of 6 per cent. copper. *(2)* Leaching followed by electrolytic precipitation or precipitation by iron, for oxidized ores. *(3)* Concentration followed by smelting of concentrate, for low-grade sulphide and native-metal ores. SMELTER TREATMENT of ores and concentrates consists in melting down in an oxidizing atmosphere, as a result of which an artificial copper-iron sulphide (MATTE) carrying precious metals is formed, rock-forming impurities are slagged off, and certain substances, *e.g.*, zinc and arsenic, pass off as fume. Coarse ore is treated in blast furnaces and fine in reverberatories. The molten matte is poured into a converter where air is blown through to drive off the sulphur as oxide and the iron is converted into an oxide which combines with silica to form slag. The copper product is a crude "BLISTER COPPER." This crude copper, in the absence of gold and silver, may be refined by further oxidation and subsequent reduction in a furnace similar to the "converter." If gold and silver are present the blister copper is refined electrolytically. Native-copper concentrate is melted down directly and the product refined in a furnace or, if desired, electrolytically. (See *Principles of copper smelting, E. D. Peters*, McGraw-Hill, 1907; *Practice of copper smelting, E. D. Peters*, McGraw-Hill, 1911; *Metallurgy of copper, Hofman and Hayward*, McGraw-Hill, 1924.)

Copper-ore Concentrators

The copper ores amenable to simple concentration are those containing native copper or sulphides of copper, to which both water-gravity and flotation concentration are applicable, and oxidized ores containing cuprite, which responds to gravity concentration from any of the usual gangues. Oxidized ores in which malachite, azurite and chrysocolla are the economic minerals do not respond to either gravity concentration or simple flotation. Sulphide-filming of the carbonates or solution of both carbonates and silicate with subsequent precipitation and flotation have been successful experimentally.

(Sec. 12, Art. 25.) Hydrometallurgical treatment of such ores is the commonest method at present (1925).

Native copper, coarse dissemination. The Champion mill of Copper Range Consolidated Mining Co. is typical of mills treating this class of ore. Hand-sorting and water-gravity concentration only are employed. Tailing is rejected at −0.25-in. and only middling products are re-ground.

Champion Copper Co. Fig. 43. (*Q*)

Location: Freda, Mich.

Ore: Amygdaloid containing an average of 37.5 lb. native copper per ton in all sizes from large masses to very small flakes.

Capacity: 2100 tons per 24 hr.

Assays, per cent. Cu: Feed, 1.87; concentrate, 65; tailing, 0.45–0.5.

Recovery: 88 per cent.

Ratio of concentration: 40 : 1.

Percentage possible running time: 95.8.

Labor: 13 tons per man-shift, total.

Power: 24 hp.-hr. per ton milled.

Water: 30 tons per ton of ore milled. No reclamation.

Distances: Mine to mill, 14 mi.; mill to smelter, 19 mi.; water transport, 1600 ft. from Lake Superior; electric power transmitted 14 mi. at 30,000 volts.

General: Sloping mill site.

Summary. Crushing: Jaw crusher, steam stamps and rolls in series from −24-in. to −0.25-in. Concentration: Hand-picking at 12-in. or larger down to 2- to 3-in.; steam-stamp classifier, 3-in. to 0.5-in.; jigs on −0.62 +0.25-in. sized feed; hydraulic classifiers followed by roughing (hutch-making) jigs and finishing tables on primary −0.25-in. feed. Fine-jig tailing discarded. Finishing-table tailing and middling re-ground in pebble mills and tabled without classification.

This relatively simple sorting and all-gravity flow-sheet is still considered best by the management for this particular ore, notwithstanding years of experimentation. Flotation, which is practiced by Calumet and Hecla, is not applicable on account of the comparative coarseness of the finest copper and the difficulty in grinding it to flotation size. The steam stamp is peculiar to Michigan native-copper mills and serves a purpose in separating the tough, irregular copper particles from the enclosing rock that no other crusher does as well.

With the exception of the elevator handling bull-jig tailing all elevation of pulps is accomplished by means of centrifugal sand pumps.

Native copper, fine dissemination. The conglomerate ores of the Lake Superior region are typical of this occurrence and the conglomerate sections of Calumet and Hecla mill illustrate an efficient treatment method. Hand picking, gravity concentration by jigs and tables and agitation-froth flotation are successively employed and sands from the re-grinding mills are leached.

Calumet and Hecla Mining Co. Conglomerate mill. Fig. 44 (*Q, 100 J 7; 117 J 277*).

Location: Torch Lake, Mich.

Ore: Native copper with a little native silver in an extremely hard rhyolitic conglomerate.

Capacity: 11,000 tons per 24 hr.

Assays, per cent. Cu: Feed (original mine ore), 1.75; concentrate, 60 to 62.

Recovery: 85 per cent (on mine rock).

Ratio of concentration: 35 : 1.

Percentage possible running time: 98, approx.

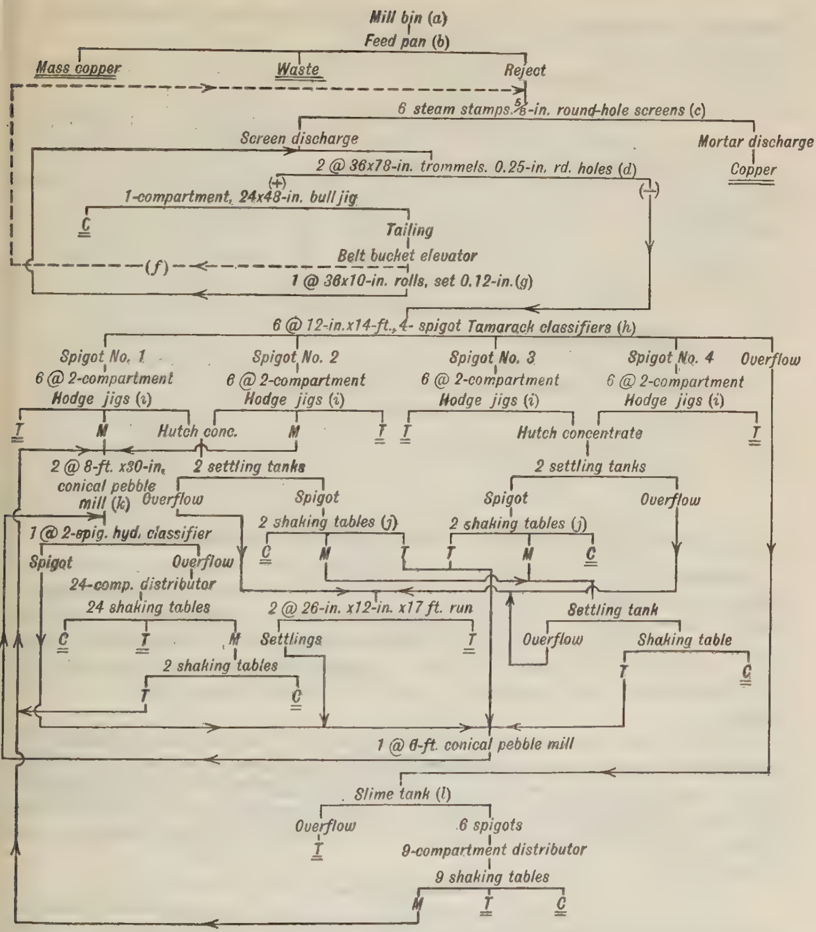
Labor: 19.5 tons per man-shift, total.

Power: 30 to 36 hp.-hr. per ton milled.

Water: 28 tons per ton milled. No reclamation.

Distances: Mines to mill: 5 mi. max.; mill to smelter, 0.5 mi.; water at mill; power transmitted 0.5 mi. at 13,500 volts.

Costs: See flow-sheet notes (*j*), (*k*), and (*s*) and Table 38.



a, 500-ton, 20 (diam.) × 44 ft. Contains −3.5-in. product of rock-house jaw crusher. (See Fig. 44 for a typical rock-house flow-sheet.) *b*, Inclined (−27°) converging chute with means for controlling flow. Operator picks waste and mass copper and regulates flow according to performance of stamp. Mass removed ranges from 6- to 12-in. size. One man picks about 110 lb. per hr. *c*, Simple (20 × 24-in. cylinder) and steeple-compound (see Sec. 3, Art. 16). *d*, 18 r.p.m. Slope, 1 in. per ft. Open-hearth high-carbon steel plate; life, 71 da. Total load, 363 tons per 24 hr.; 12,500 gal. water per hr. About 35 per cent. undersize in oversize. *f*, Alternative emergency flow. *g*, See Sec. 3, Table 22. *h*, Feed contains 80 per cent. water; spigot products, in order, 80, 83, 87 and 85 per cent., and overflow 96 per cent. water. Spigot apertures: No. 1, ¾-in. pipe, worn; No. 2, ¾-in. pipe, new; No. 3, ½-in. pipe, worn; No. 4, ½-in. pipe, new. Attendance, for 6 machines, one man part time. *i*, 24 × 36-in. compartments. (See Sec. 9, Art. 5.) *j*, See Sec. 10, Art. 11. *k*, See Sec. 4, Art. 16. *l*, 45 ft. long, 7 ft. deep, 9 ft. wide. *C*, Finished concentrate, to smelter. Moisture, 7.5 per cent. *T*, Finished tailing, combined and laundered to lake.

Fig. 43.—Champion Copper Co.

Table 38. Performance of flotation machines in Calumet and Hecla reclamation plant. (*After Benedict*)

Representative sample

	Feed		Tailing, Cu, per cent.	Recovery, per cent.
	Weight, per cent.	Cu, per cent.		
+200-mesh	6.0	0.289	0.243	15.9
−200-mesh	94.0	0.516	0.157	69.6
Total	100.0	0.502	0.162	67.8

Averages and totals, 1923

Feed, per cent. Cu	0.453
Tailing, per cent. Cu	0.164
Concentrate, per cent Cu	28.58
Recovery, per cent	63.89

Costs, 1923

General expense	$0.0278
Slime conveying and distribution	0.0280
Flotation	0.0547
Royalty	0.0449
Total	$0.1554

Cost per pound of copper produced, excluding smelting and selling, $0.0270.

Summary. No receiving bin. Crushing: Jaw crusher, 24- to 3-in.; steam stamp, 4- to 3/16-in.; pebble mills, 3/16-in. to 35-mesh. Concentration: Hand-picking on sizes to −3-in.; jigging in stamp mortar and on natural product through 3/16-in. screen with cleaning of jig-hutch product on shaking tables. Fine sands tabled without classification. Gravity-concentration residues divided into sands and slimes, the former leached and the latter floated.

Compare with the Copper Range flow-sheet. The copper in conglomerate ores is more finely disseminated than that in amygdaloid ores and is, therefore, less amenable to table concentration and more readily recoverable by flotation. Leaching eliminates the necessity of re-grinding all gravity-concentration tailing to flotation size and makes better extraction of coarse copper than flotation does.

Notes to Fig. 44.

a, Tilting pan, 9 ft. wide at upper end, 4 ft. at lower, with double-curved bottom. Head end is lowered below sliding angle of rock to receive grizzly oversize from dumped skip and raised by means of chains from friction-clutch drum on main line shaft after material has been picked. Pan bottom of ¾-in. plate, sides of ½-in. plate, all lined with ⅜-in. plate. 2 men required per shift, one picking and one operating winch. *b,* See Sec. 3, Table 10. *c,* 400-ton live capacity. One for each steam stamp. *d,* 28 of these. Capacity on conglomerate, 335 to 350 tons each per 24 hr. 3 tons water per ton of ore. (See Sec. 3, Table 28.) *e,* Four per stamp. 4 × 12-in. sieve compartments, 1-in. screens, 190–200 @ 2-in. strokes per min. *f,* See Sec. 9, Art. 5. First sieve 36 × 48-in., others 30 × 48-in. *g,* For 17 mill units. *h,* Capacity, 2640 tons per 24 hr. *i,* See Sec. 4, Table 77. *j,* Old mill tailing. 0.5 to 1.0 per cent. Cu. Total cost (1923) per ton of solid treated, including proportion of mine and mill administration:

General administration and miscellaneous	$0.044
Dredge (note *k*)	0.063
Shore plant (note *s*)	0.025
Re-grinding (note *s*)	0.164
Leaching	0.251
Flotation	0.034
Total	$0.581

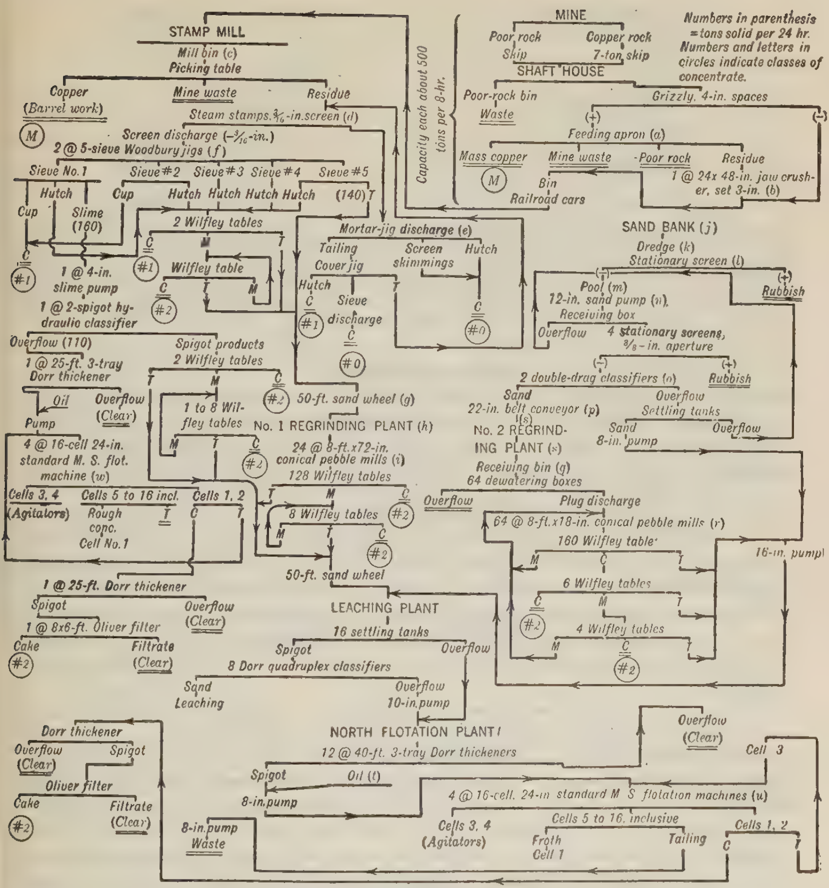


FIG. 44.—Calumet and Hecla, conglomerate mill.

Tons treated, 1,743,100. Assays, per cent. Cu: feed, 0.608; tailing, 0.124. Recovery, 80 per cent. *k,* Suction type. 10,000-ton daily capacity. 20-in. pump with 1250-hp. motor discharges through 3000 ft. of 20-in. pipe on pontoons to receiving pool on shore. Can dredge to 110 ft. below water level. COST (1923) for dredge operation with discharge through average length of 2000 ft. was $0.063 per ton of solid dredged. Distribution was: labor, 32 per cent.; power, 40 per cent.; pump renewals, 14 per cent.; other supplies, 14 per cent. *l,* On shore. 16 × 20 ft., 1-in. round holes. *m,* Capacity, 20,000 tons sand. *n,* Swinging suction of constant length giving uniform feed to re-claiming plant. Casing is split horizontally and lined throughout. Impeller 40-in. diam., direct-connected to 200-hp. motor. *o,* Each with 2 @ 20-in. belts carrying 6 × 4 × 24-in. angles. *p,* 275 ft. long; slope, 2½ in. per ft.; speed, 500 ft. per min. *q,* About 30-min. storage capacity. Discharged through gates by means of water jets. *r,* Capacity of 64 mills, 3000 tons per 24 hr. (See Sec. 4, Table 77.) 40-hp. motor each with flexible coupling and herringbone gears. Mills served by 15-ton crane that can pick up a full mill; time to change about 1 hr. *s,* Cost (1923) from pool to re-grinding plant was $0.0247 per ton of sand, of which cost 45 per cent. was labor, 30 per cent. power and 25 per cent. supplies. Cost per ton in re-grinding plant was:

General expense		$0.0182
Sand conveying and distribution		0.0186
Grinding:		
Labor	$0.0137	
Power	0.1363	
Pebbles and lining	0.0938	
Other supplies	0.0089	
		0.2527
Table treatment		0.0400
Total		$0.3295

Metallurgical results (1923): tons treated, 866,524. Assays, per cent Cu: feed, 0.723; tailing, 0.468, concentrate, 60. Recovery, 35.5 per cent. Cost per pound of copper, excluding smelting and selling, $0.064 (1923). About 1.5 lb. per ton of a mixture of coal tar from a local gas plant, Barrett coal-tar creosote, Semet Solvay residual coal-tar oil, Cleveland Cliffs wood creosote, and a little pine oil as required for frothing. No acid nor heat. u. Feed contains 25 per cent solids, enters 3rd cell. See also Table 38. a. See Table 38. Pulp fed to cell No. 3.

Copper-sulphide ores, coarse dissemination. The ANACONDA mill is typical of the old-style graded-crushing and gravity-concentration plant, with flotation added later. The antithesis is the Nacozari mill (MOCTEZUMA COPPER CO.), treating a somewhat similar ore and formerly making a similarly low-grade pyritic concentrate but now, with gravity concentration discontinued, eliminating the pyrite by selective flotation and making high-grade concentrate with substantially no loss in recovery and a new financial gain. The CHINO mill has been completely remodeled since the introduction of flotation, but gravity concentration had to be retained to scalp out oxidized copper minerals not amenable to flotation. At the ARIZONA HERCULES mill a similar concentrating problem is solved in a unique manner, by installing Harz jigs to treat the sand in the ball mill-classifier circuit. The BRITANNIA M. AND M. mill uses Hancock jigs to remove 5 to 8 per cent. of the feed at −0.25-in.

In general, with coarsely disseminated copper ores gravity concentration should precede flotation. Its use will probably increase recovery to some extent, even with non-oxidized ores, and will surely do so, if native copper and copper oxides are present; it will take some of the burden off the flotation machines, thus probably lessening the number required, and will simplify their operation; the granular concentrate from the gravity machines will decrease the amount of concentrate-dewatering equipment required and lower the moisture content of the concentrate as a whole; finally the product shipped will be easier to smelt. The disadvantages of including gravity concentration are increased complexity of flow-sheet and the addition of water on the gravity-concentrating machines, which water must be eliminated before flotation. These disadvantages are, in most cases, outweighed by the advantages listed. At the Nacozari mill the improvement in grade of concentrate by selective flotation over that obtainable by gravity concentration was an added advantage to the all-flotation flow-sheet which is not ordinarily present.

Anaconda Copper Co. Fig. 45. (PC.) Section 2. Nov. 1, 1923.

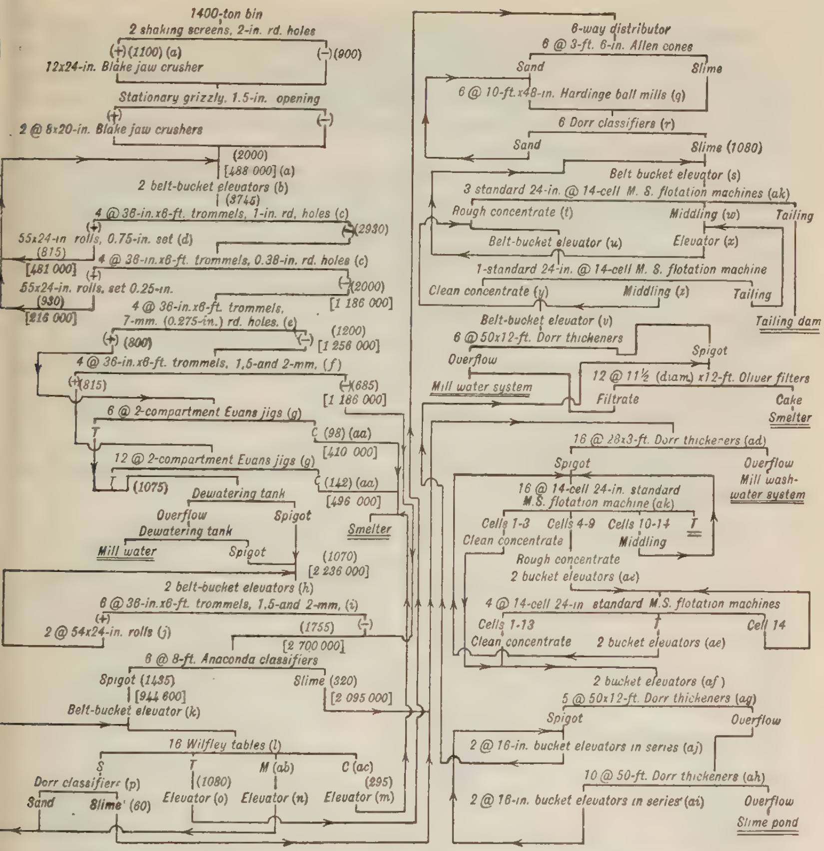
Location: Anaconda, Mont.

Ore: Bornite, chalcocite, chalcopyrite and pyrite coarsely disseminated in granite gangue.

Capacity: 2000 tons per section per 24 hr. 8 sections, [illegible]. Average daily mill tonnage, 15,000.

Assays, per cent Cu: Feed, 3.0 to 3.2; concentrate, 12 to 17; tailing, [illegible]

General: Ore from a group of underground mines at Butte, Mont., is hauled 32 miles in 50- and 60-ton standard-gage gondola cars to the mill at Anaconda, Mont.



a, Numbers in parenthesis are tons solid per 24 hr.; numbers in brackets are gallons of water per 24 hr. *b*, 461 ft. per min. 144 ft. of 18-in. @ 10-ply belt; 123 @ 8 × 16-in. buckets. *c*, 30 r.p.m. *d*, 85 r.p.m. *e*, 20 r.p.m. *f*, 2 × 12- and 1.5 × 12-mm. apertures. 20 r.p.m. *g*, 20 × 40-in. sieves, 8-mesh. *h*, 550 ft. per min. FIG. 45.—Anaconda Copper Co.

Summary. Receiving bin. Jaw crusher, 12- to 3-in.; jaw crusher, 3- to 1.5-in.; rolls, 1.5- to 0.75-in.; rolls 0.75- to 0.25-in.; rolls, 0.25- to 0.08-in.; one-stage ball milling, 2-mm. to 48-mesh. Screening between crushing steps and to prepare for jigging; hydraulic classification ahead of shaking tables. All sand tailing re-ground for flotation. Primary slime sent to separate flotation cells.

This plant is typical of large-tonnage, gravity-concentration plants with careful graded crushing and step concentration and flotation added at the end to recover sulphide mineral from the slimes. Compare with MOCTEZUMA COPPER CO. Concentrate is low-grade (about 10 to 12 per cent. Cu) on account of the large amount of pyrite present, but as the Anaconda Company also owns and operates the smelter and manufactures sulphuric acid both for its own hydrometallurgical uses and for sale, the pyrite is not objectionable. It is probable that were this mill to be built anew to-day jigs would be eliminated, the table feed would not be classified, and pneumatic flotation machines would be used.

Moctezuma Copper Co. (Phelps Dodge Corp.) Fig. 46. (*Q, 118 J 445.*)

Location: Nacozari, Sonora, Mex.

Ore: See Table 39. Chalcopyrite and copper-free pyrite in hard latite, andesite, monzonite, diorite and quartz porphyry.

Table 39. Analyses of feed, concentrate and tailing, Moctezuma Copper Co.

a Questionnaire, 1919. *b* Composites, May, 1924. (*118 J 452.*)

Capacity: 3000 tons per 24 hr.

Assays: See Table 39.

Recovery: 92 to 94 per cent.

Ratio of concentration: 10 or 12 to 1.

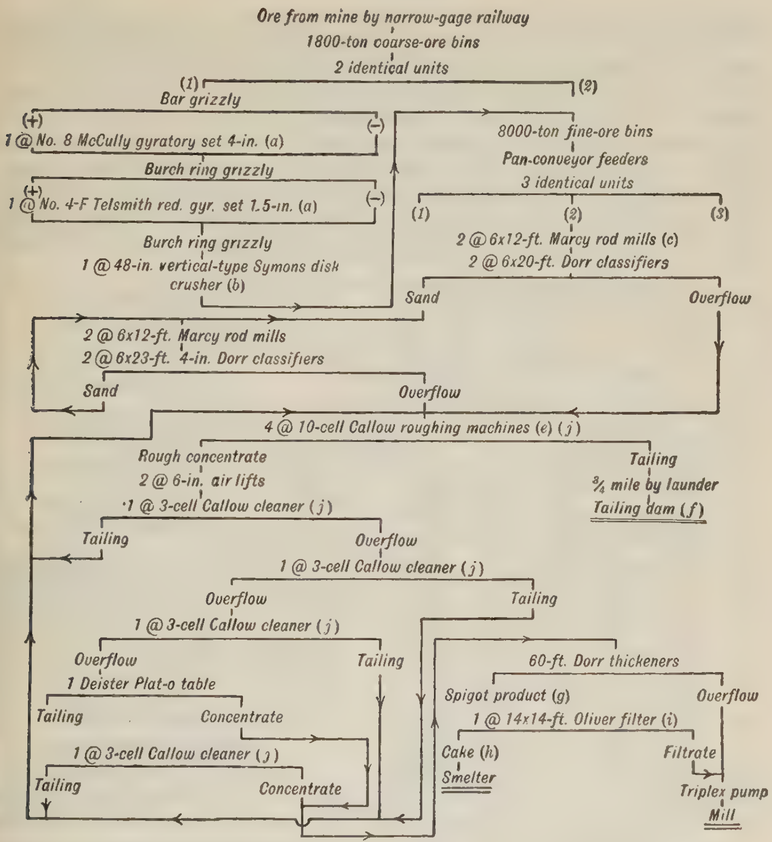
Percentage of possible running time: 97 per cent.

Labor: 31 tons per man-shift on operation; 75 per man-shift on repairs; 22 tons per man-shift, total.

Power consumption, hp.-hr. per ton: Coarse crushing, 1.1; all conveying ahead of rod mills, 0.7; two-stage grinding in rod mills, 12.5; flotation, including air lifts, 3.2, total, 23.2.

Water: 900,000,000-gal. reservoir with gravity flow to mill. Consumption: total, 1200 gal. per ton; reclaimed, 750 gal. per ton.

Distances: Mine to mill, 5 mi.; mill to smelter, 78 mi.; water, 3½ mi.; power, 1 mi.



a, See Sec. 3, Table 15. *b*, Product, 35 per cent. on 0.5 in. *c*, Product, −10-mesh. *e*, Feed − 48-mesh. Each bottom 42 × 42-in. canvas. Depth, 17 in. at head end to 26 in. at lower end. Flotation agents: 0.05 lb. crystalline potassium xanthate, 0.19 lb. steam-distilled pine oil; 5.5 to 6.5 lb. lime per dry ton of original mill feed. Best results are obtained when the tailing shows a lime equivalent of 0.15 to 0.35 lb. CaO per ton of clear solution and this is maintained by the operators by frequent titration. Soda ash, sodium silicate and other alkalis proved inferior. *f*, Now 105 ft. high. Sand placed by an overhead launder with de-sanding cones. *g*, 60 per cent. solids. *h*, 13 per cent. moisture. *i*, Change to xanthate and selective flotation has reduced filter requirement from three. *j*, The gradual elimination of iron and insoluble in a closely similar flow-sheet is shown in Fig. 47.

Fig. 46.—Moctezuma Copper Co.

Summary. Crushing by jaw and gyratory breakers and two sets of rolls in series from steam-shovel size to −8-mesh. Roughing-cleaning system of shaking-table concentration on −8-mesh primary feed and in re-grinding mill circuit. No gravity-concentration tailing made. Flotation by roughing-cleaning system with re-cleaning of concentrate.

This mill has been extensively remodeled since the introduction of flotation, but gravity concentration has been retained both on account of the

granular character of some of the sulphide and because of the presence of native copper, copper oxides and copper carbonates. The mill as originally built provided for graded-crushing, jigging the coarse sizes, with step hydraulic classification and treatment of classified products on shaking tables and vanners. Recovery by this method (1913) from 2-per cent. ore was 67.3 per cent.; ratio of concentration, 10.6 : 1; concentrate assay, 14.52 per cent. Cu. Iron content of ore was exceptionally high. In 1914 recovery was 73.4 per cent. and concentrate assayed 27.7 per cent. Cu. Capacity was about 6000 to 7000 tons per 24 hours. Capacity of the remodeled plant is about double this (12,000 to 14,000 tons per 24 hours), and recovery on feed containing only 1.5 to 1.6 per cent. Cu is between 75 and 80 per cent.

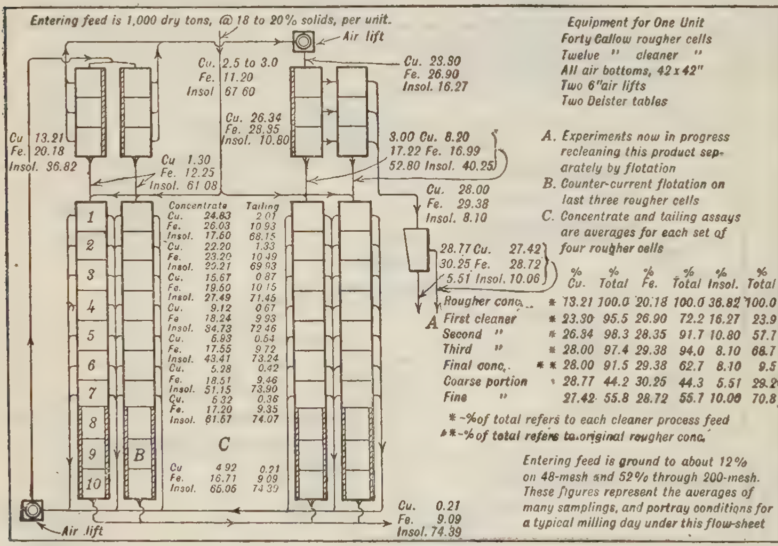


FIG. 47.—Interim assays in the flotation plant at MOCTEZUMA COPPER CO. (*after McDonald*).

Chino Consolidated Copper Co. Fig. 48. (*117 J 13, Q.*)

Location: Hurley, N. M.
Ore: Chalcocite and pyrite with some native copper and oxidized copper minerals in quartzite, diorite, porphyry and various metamorphic rocks (*116 J 984*)
Capacity: 12,000 tons per 24 hr.
Assays: Feed, 1.65 per cent. Cu; concentrate, 15.46 per cent; tailing, 0.554 per cent.
Recovery: 79; ratio of concentration, 13.6.

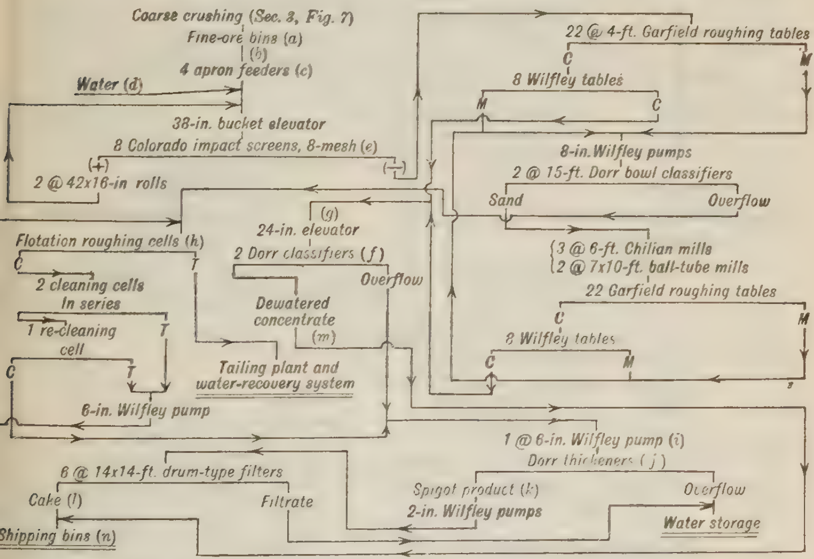
Britannia M. and M. Co. Fig. 49. (*28 MM 316; 115 J 375; 113 P 693.*)

Location: Howe Sound, Brit. Col.
Ore: Chalcopyrite and pyrite with a little sphalerite and galena in chloritic schist.
Capacity: 2500 tons per 24 hr.
General: Steeply sloping mill, six floors, 191 ft. high (216 ft. to the top of the receiving bins).

Summary. Underground crushing to −2.5-in.; 2-step reduction in rolls from 2.5- to 0.25-in.; closed-circuit tube milling to flotation size. CONCEN-

TRATION: Jigging at −0.25-in., flotation of primary slimes and re-ground jig tailing. Concentrate-middling routing.

Copper-sulphide ores, fine dissemination. Four general types of flow-sheets are employed in treating this class of ores, viz: *(1)* all-flotation; *(2)* gravity concentration followed by flotation; *(3)* flotation followed by gravity concentration; *(4)* flotation preceded and followed by gravity concentration. The first class is illustrated by the Magna mill of UTAH COPPER CO., the Superior mill of the ENGELS COPPER MINING CO., the No. 1 concentrator of the MOUNTAIN COPPER CO., the MIAMI COPPER CO. plant, and the MT. LYELL mill. The UTAH LEASING CO. mill, treating a dump tailing which is, artifi-



a, Cylindrical steel, 24 ft. 6 in. (diam.) × 40 ft. Two to a section, 14 in all. Live capacity 1000 tons each per 24 hr. *b,* One section. *c,* Two to a bin. *d,* 1.2 tons per ton of ore. *e,* 0.089-in. wire, 0.087-in. aperture. *f,* 4-ft. 6-in. duplex with vacuum trays and air jets. *g,* When magnetite is excessive in amount or is wanted for sponge iron, this concentrate is run to 3 drum-type magnetic separators. Sec. 13, Art. 13. *h,* Eight rows of Janney mechanical-air machines, each row with six agitating compartments (two ahead of the first air basket) and five @ 2 ft. 6 in. × 10-ft. air-basket compartments. *i,* Serves 1½ units. *j,* 5 @ 75 × 20 ft. and one @ 48 × 20 ft. *k,* 50 per cent. moisture. *l,* 20 per cent. moisture. *m,* 8 per cent. moisture. *n,* 17 per cent. moisture.

FIG. 48.—Chino Consolidated Copper Co.

cially, a finely disseminated ore, is of this same type. The mill at BRADEN COPPER CO. and the remodeled mill at the Morenci branch of PHELPS DODGE CORP. illustrate variants of the second type. INSPIRATION and CONSOLIDATED COPPERMINES are typical of the third class and the new Copper Queen concentrator of the PHELPS DODGE CORP. the fourth.

Utah Copper Co., Magna plant. Fig. 50. *(6 MMt 414; PC.)*

Location: Garfield, Utah.
Ore: Chalcocite and pyrite with a small amount of chalcopyrite in granitic porphyry.
Capacity: 25,000 tons per 24 hr.

Distances: Mine to mill, 18 miles; mill to smelter, 2 miles.
Cost of crushing: see note *v*.
For cross-section of crushing plant see Fig. 51.

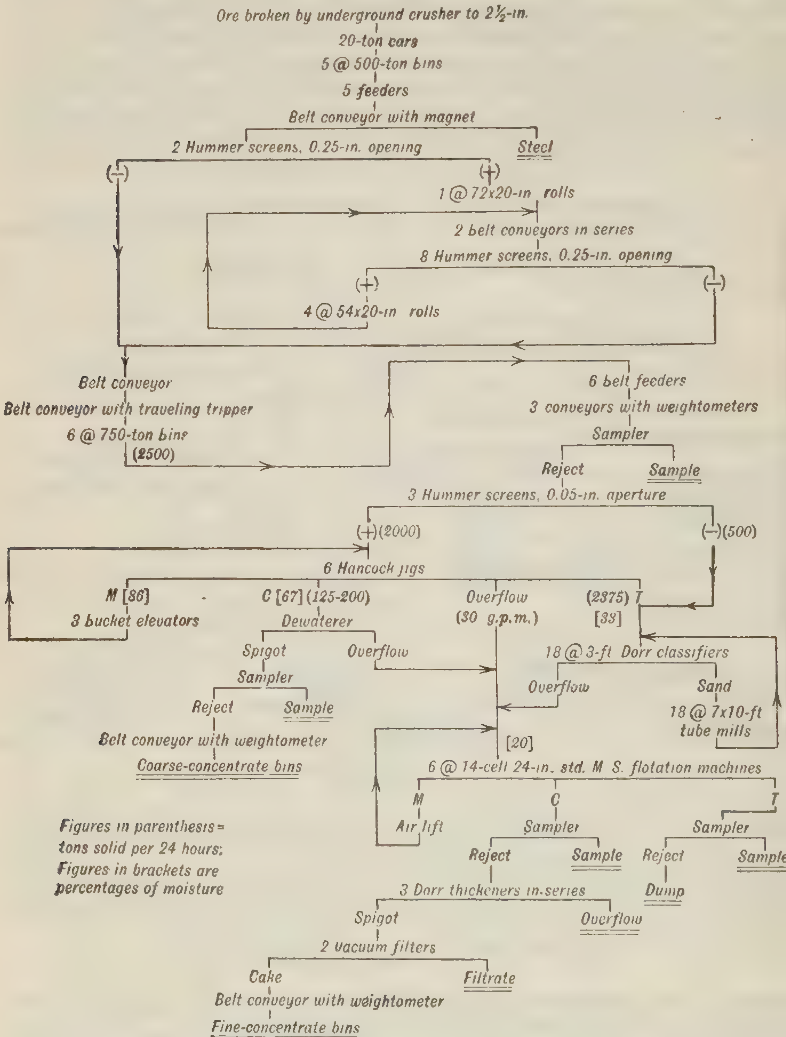


Fig. 49.—Britannia M. and M. Co.

Summary. No receiving bin. CRUSHING: gyratory, 54- to 6.5-in.; gyratory, 6.5- to 2.5-in.; rolls, 2 sets in series, 2.5- to 0.75-in. Circuit is closed on second rolls with impact screens. Rolls from 0.75- to 0.25- or 0.37-in. in closed circuit with impact screens. One-stage ball milling. All transport and

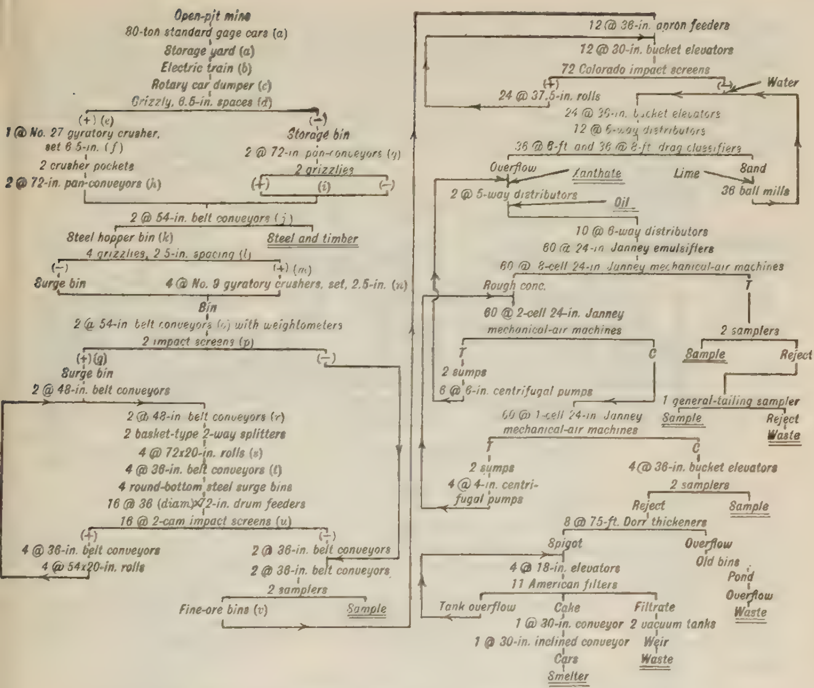

FIG. 50.—Utah Copper Co., Magna plant.

a, 45-car trains from mine to a 3-track loaded-storage yard with overhead trolley system. Storage capacity, 140 cars permanent and about 200 between train arrivals. Usual amount of ore in storage varies from 25 to 150 cars (2000 to 12,000 tons). ***b,*** 10- to 12-car trains hauled by electric locomotive and spotted two at a time in car dumper. Empties go by gravity to a 200-car, 3-track electrified empty-storage yard. Switching crews of 4 men. Two crews needed in summer and three in winter for medium tonnage. ***c,*** Two one-car units; may be operated separately or together. 50-hp. motor to each unit. 165° revolution. Dumper cycle is 2 min., but average time per car including spotting is 5 min. ***d,*** Dumped ore received on a pile of ore (see Fig. 51) which feeds two grizzlies side by side, each 1 car-length in width, 20 ft. long, sloping 42° from the horizontal. Each bar is a 20-in. T-beam capped with manganese-steel wearing plates. ***e,*** Estimated, 25 per cent. ***f,*** 54-in. gape, 2-way discharge, 250-hp. @ 300 r.p.m.; motor coupled direct to pinion shaft by flexible coupling. ***g,*** Driven by 2-speed motors. Controls tied in with controls of following belt conveyors, but feeder motors can be cut out independently by a push button. ***h,*** Driven by roller chain and sprocket through friction clutch from 54-in. belt-conveyor drive. ***i,*** Fines first onto belt. Crusher-pocket products come on after grizzly products. Object is to prevent cutting by large lumps. ***j,*** Each belt conveyor is fed by two pan conveyors, one each from a crusher pocket and the storage bin. Conveyors have ball-bearing troughing and return idlers. Slope, +19°. Each conveyor is driven through double-reduction gears by a 125-hp. 2-speed motor, fitted with automatic solenoid brake on a drum attached to the rotor shaft, in order to prevent the conveyor from running backward when stopped under load. Push buttons for starting and stopping are located near the head pulley and a button for stopping near the tail pulley. Speeds, 175 and 350 ft. per min., which allows one conveyor to take the full load when necessary. Steel and timber picked near head pulleys. ***k,*** For distributing purposes only. ***l,*** Standard manganese-steel T-bars. Each grizzly 6 ft. wide × 12 ft. long with bars spread slightly at the bottom. Slope, 42°. Spacing in summer, with dry ore, 1.25 in.; in spring and winter with wet and frozen ore, 2.5 in. ***m,*** About 30 per cent. of total. ***n,*** Short-head type. Direct-driven through flexible coupling by 125-hp. @ 450-r.p.m. motor. Normal control equipment at each motor and

cut-out buttons on the feed floor. Forced-feed lubrication with water-cooling for the circulating oil. An external oil-pumping and filtering system is provided for treating oil from all crushers. *o,* Ball-bearing idlers 6 sets of side idlers, equally spaced Head-pulley drive 50-hp motor each, 2-speed, double-reduction gears, flexible coupling, push-button control with stop buttons spaced at regular intervals along belts. Recording weightometers near head pulley. Moisture sample taken at head pulley. *p,* Opening varies from 1 in. square on dry ore to 1.5 × 3 in. on wet ore. Specially designed 4-cam

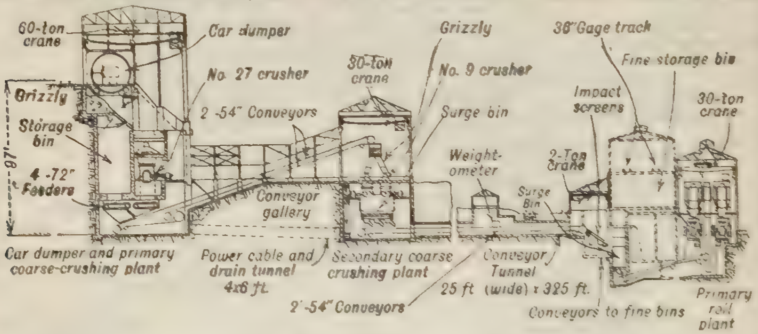

FIG. 51.—Coarse-crushing plant, Utah Copper Co., Magna mill.

screens. *q,* About 60 per cent. *r,* Incline, +21°. 420 ft. per min. Ball-bearing troughing and return idlers. Tandem drive. 100-hp. motor each with flexible coupling and reduction gears. *s,* Belt driven from line shaft, which is direct-driven through flexible coupling by a 250-hp. @ 300-r.p.m. motor. *t,* Slope, +21°. 370 ft. per min. Drive similar to 48-in. (note *r*) except 50-hp. @ 670-r.p.m. motors used. *u,* Aperture varies between 0.75 and 1 in. sq., as ore is dry or wet respectively. 1 @ 5-hp. motor to four screens. *v,* Cost (excluding overhead) for crushing to this size on average tonnage in 1925 was as follows:

	Per ton
Operating labor	$0.01053
Power	0.00828
Maintenance, labor and supplies:	
Car dumper	0.00072
Gyratory crushers	0.00294
Feeders and conveyors	0.00747
Screens	0.00173
Rolls	0.00737
Total	$0.03904

elevation in coarse-crushing plant by belt conveyors. CONCENTRATION: All-flotation. Rougher-cleaner routing. Concentrate cleaned twice.

This plant, built about five years later than the Arthur plant of the same company, is of interest in showing the retention of gyratories and rolls for crushing and of all-conveyor transport, but substitution of impact screens for 0.75-in. screening in place of the vibrating screens (Mitchell type) in the earlier plant. The impact type is the more rugged and the amplitude of vibration is greater. The later plant also contains more bins or hoppers in the course of the flow, which insures a more regular feed to all machines following the initial crusher and, therefore, better operation. The new plant uses more rolls and those for final crushing are of smaller diameter than in the old plant. This is in line with usual practice.

Engels Copper Mining Co., Superior mill. Fig. 52. (*Q; 123 P 183; 111 J 904*)

Location: **Engelmine, Calif.**

Ore: Very hard and tough. Altered diorite with bornite, chalcopyrite, chalcocite and covellite; some malachite and chrysocolla near surface.

Capacity: Have treated 1200 tons per 24 hr. on flow-sheet given. Average, 30,000 tons per month.

Assays: Feed, 2.25 per cent. Cu; concentrate, 30 per cent. Cu, 8 oz. Ag, 0.1 oz. Au; tailing, 0.45 per cent. Cu.

Recovery: 81 per cent.

Ratio of concentration: 15 : 1.

Labor: 30 tons per man-shift, operating; 130 tons per man-shift, repairs.

Water: 3.5 tons per ton of ore milled, none re-used. Transported 4½ miles by flume.

Percentage possible running time: 90.

General: Two mines, one at mill, the other 2½ miles away, deliver ore by aerial tram. Concentrate with 12 per cent. water shipped 600 miles to Garfield, Utah.

Arrangement: Steep mill site. See Fig. 53 for section of mill.

Flotation agents: 26 per cent. fuel oil, 53 per cent. Diesel oil (24° Bé. California fuel oil), 21 per cent. No. 14 Georgia pine; 80 per cent. added at ball mills; balance to tube mills and head flotation cells.

Metallurgical data, 1920: Tons milled, 239,612; lb. concentrate, 28,799,769; assays as above.

Costs: 1920: See Table 40.

Table 40. Milling costs at Engels Copper Mining Co., 1920

Total	$0.9303	$0.3103	$1.2407

Summary. CRUSHING: Jaw crusher, 16- to 5-in.; gyratory, 12- to 3-in.; gyratory, 3.5- to 1.5-in.; rolls, 2- to 0.75-in.; 2-stage ball milling from −2-in. and −1-in. (in parallel) to 65-mesh. CONCENTRATION: Flotation by a complex roughing-cleaning routing using both agitation-froth and pneumatic machines for roughing and pneumatic for cleaning and re-cleaning.

This plant is illustrative of the most favorable type of sloping mill site; the hill is steep and there is solid bed rock practically at the surface so that foundations are small and few retaining walls are necessary. With the exception of the inclined conveyor from the secondary gyratories to the trommel, the elevator closing the circuit on the rolls, and the pumps for circulating flotation pulps, the products flow by gravity from feed bin to concentrate bin and tailing dam. The mill is set higher on the hillside than otherwise necessary in order to provide head-room for tailing disposal one mile distant. As a result concentrate must be lowered from filters to the shipping bin at considerable inconvenience on account of spill. A better design would have placed the filters just above the shipping bins with thickened filter feed flowed down hill in pipes or launders. At MIAMI both thickeners and filters are placed at the bottom of the hill and unthickened concentrate is flowed to

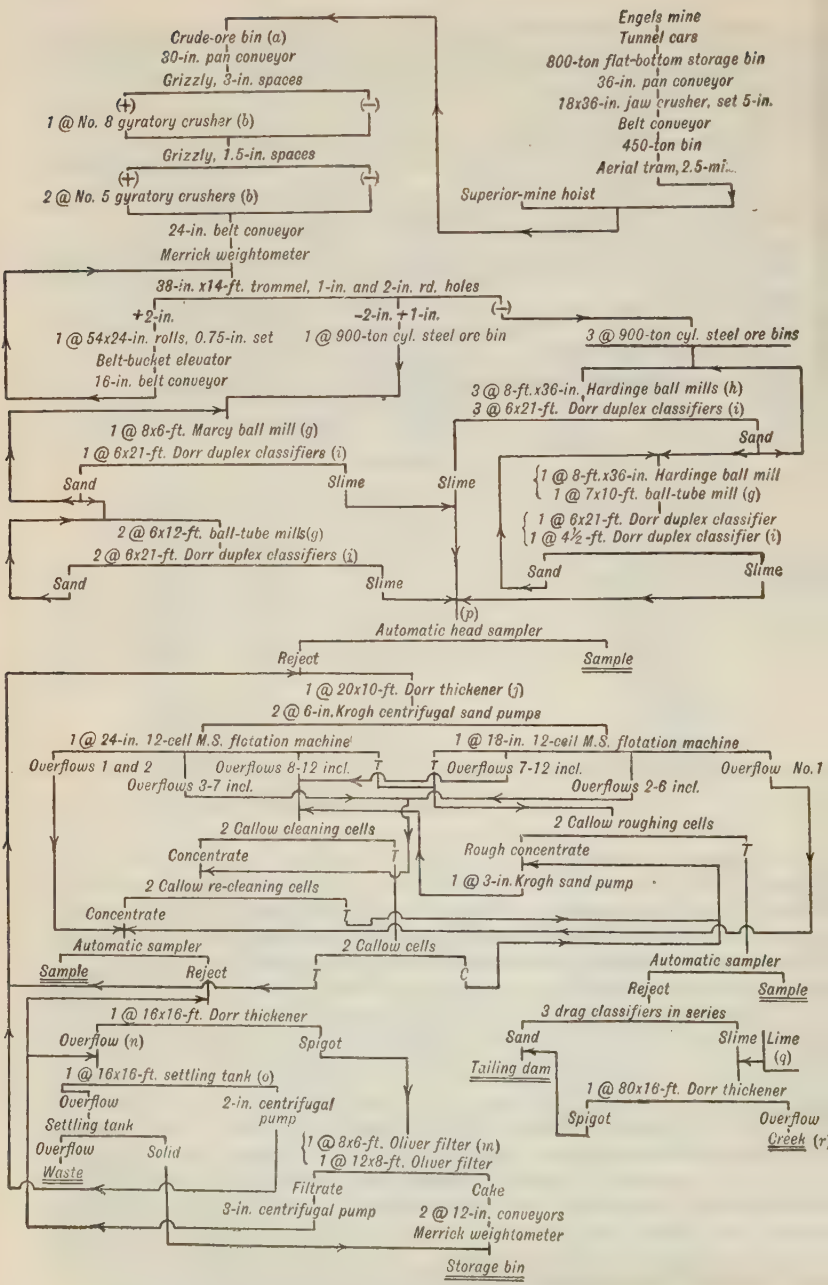

FIG. 52.—Engels Copper Mining Co., Superior mill.

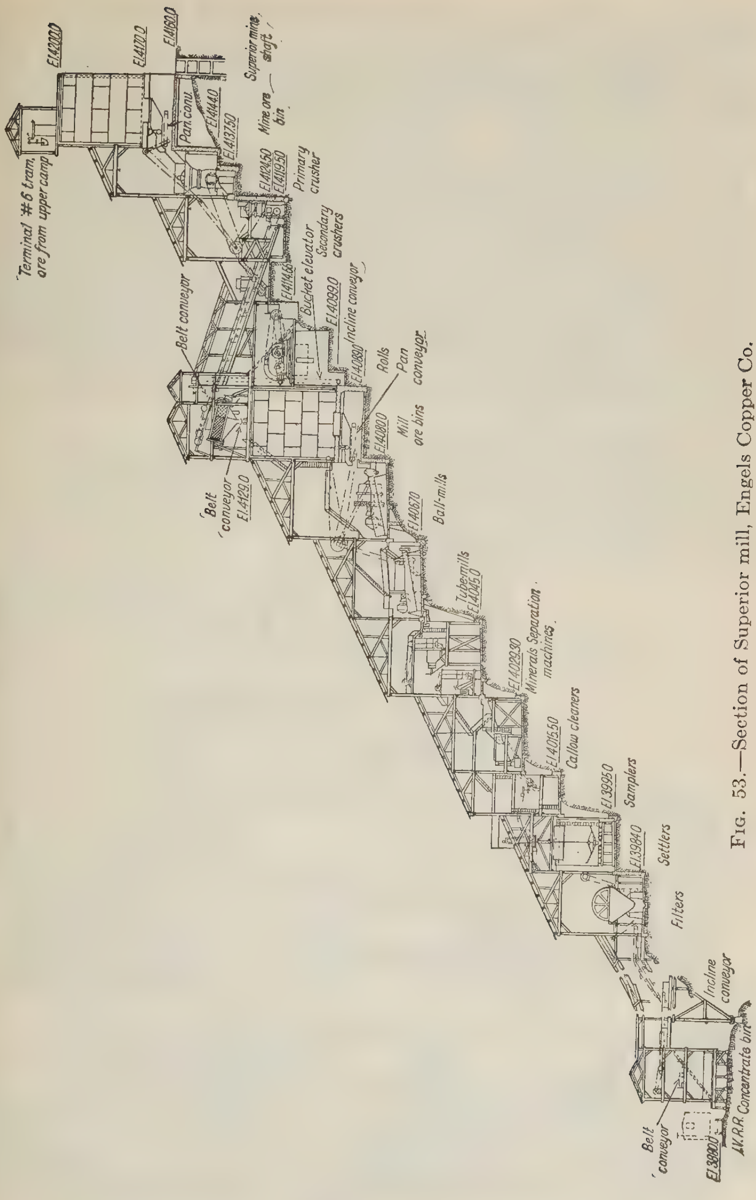

FIG. 53.—Section of Superior mill, Engels Copper Co.

the former. Outside inclined tramways, one each side of the mill, serve the different floors, at considerable expense.

Careful experimental work has proved that by crushing all ball-mill feed to pass 1-in. ring one ball mill followed by two tubes could grind 866 tons per day to 10 per cent. + 100-mesh at an expenditure of 10.7 kw.-hr. per ton ground against 444 tons for one ball and one tube mill, consuming 15.1 kw.-hr. per ton ground, according to the flow-sheet shown.

Notes to Fig. 52.

a, Cylindrical, steel, 24 ft. 6 in. (diam.) × 30 ft., flat-bottom, 837 tons live capacity. ***b,*** See Sec. 3, Table 15. These crushers have suffered undue breakage, probably due to iron. Cobbing magnets have now been put in ahead of the crushers. ***g,*** See Sec. 4, Table 5. ***h,*** See Sec. 4, Table 11. ***i,*** See Sec. 6, Table 40. ***j,*** Feed contains 33 per cent. solids; no overflow, acts as equalizer; 1.03 r.p.m.; draws 2.6 hp. This surge tank is a marked aid to good work in the flotation cells. ***m,*** The larger filter is sufficient. The smaller one is a reserve. ***n,*** Purposely cloudy in order to remove semi-colloidal silicious material that clogs filters. ***o,*** Has no rakes. Discharged intermittently. ***p,*** 10 per cent. + 100-mesh most economical. Finer grinding gives higher recovery but causes trouble in filtering, yields a wet cake, and in the final analysis costs more than the increased saving. ***q,*** Added as emulsion. 1.75 lb. per ton of original feed. ***r,*** Dewatering and clarification compulsory. Cost \$0.17 per ton of ore milled in 1920.

Mountain Copper Co., No. 1 Concentrator. Fig. 54. *(119 P 331.)*
Location: Shasta Co., Calif.
Ore: Chalcopyrite and pyrite in alaskite-porphyry gangue.
Capacity: 550 tons per 24 hr.
Assays: Feed, 2 per cent. Cu and 8 per cent. Fe; concentrate, 15 per cent. Cu.
Recovery; 92 per cent.
Ratio of concentration: 7 : 1.
Labor: 27.5 tons per man-shift (*e*) (*k*).
Power: 25.8 hp.-hr. per ton, installed.

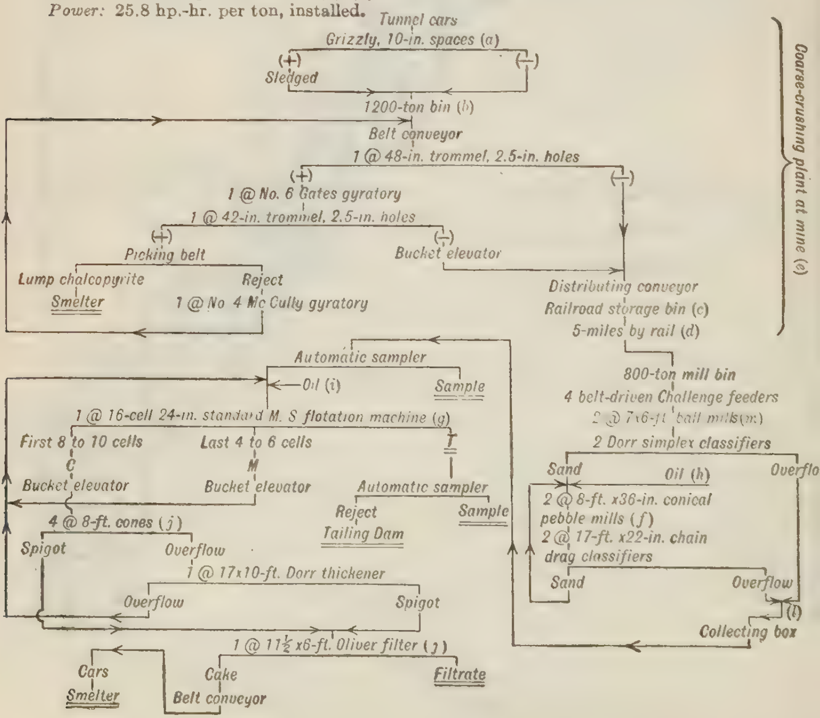

Fig. 54.—No. 1 concentrator, Mountain Copper Co.

a, 30-lb. rails over bin. One man sledges oversize through. *b*, 6 feed gates. One feeder man. *c*, 700-ton capacity. *d*, Narrow-gage track. Train: 1 Shay engine and 7 @ 20-ton cars. *e*, Capacity, 690 tons in 8 hr. Crew: 1 foreman, 1 oiler, 1 feeder, 1 roustabout, 1 grizzly man, 3 pickers. 100-hp. motor drives entire plant. *f*, Wedge-bar liners last 10 mo. in cylindrical and adjoining conical portion. Liners near trunnions last much longer. Mills not unloaded for liner renewal. Herringbone pinions last 22 to 26 mo. Consumption of California pebbles, 6 to 7 lb. per ton. *g*, Repairs for 2-years' operation total two sets of impellers, 2 sets of impeller-box liners and 1 set of regulating valves. Feed about 30 per cent. solid. *h*, Average 0.8 lb. per ton of ore: about one-half kerosene-acid sludge, balance a mixture of crude turpentine, tar oil and light fuel oil. *i*, Added to impeller boxes when needed. *j*, Entire flow to one cone until filled, then diverted to others in rotation. One purpose is to provide storage so that filter is run only half time. Principal purpose is to separate coarser concentrate, amounting to 75 per cent., which, when filtered separately, forms a 2- or 3-in. cake with 9 per cent. moisture. Dorr-thickener discharge forms ¾-in. cake with 14 per cent. moisture. If entire concentrate is sent to filter, cake carries 13 per cent. moisture. Settled concentrate in cones is loosened slightly with high-pressure water and then "boiled" with compressed air for 5 or 10 min. before filtering. It then draws readily. *k*, Mill crew: 1 flotation operator, 1 oiler, 1 man full time on concentrate handling and 1 man half time, the balance on sampling, repairs, etc.; 3 roustabouts on day shift, 1 foreman: total crew for 3 shifts, 12 men. *l*, Not over 4 per cent. −60 mesh. *m*, 4- and 5-in. chrome-steel balls, consumption, 1.8 to 2 lb. per ton. Chrome-steel liners last 4 mo.

Summary. Crushing: 2 gyratories in series, 10- to 2.5-in. in closed circuit with a trommel; 2-stage grinding in ball and pebble mills to 4 per cent. −60-mesh, ball mills in open circuit. Concentration: All-flotation, concentrate-middling routing, one agitation-froth machine.

Miami Copper Co. Fig. 55.

Location: Miami, Ariz.
Capacity: 7000 tons per 24 hr.
Ore: Chalcocite and pyrite finely disseminated in granitic schist.
Assay, per cent. Cu: Feed, 1.60 to 1.90; concentrate, 35 to 45; tailing, 0.1 to 0.15 sulphide; 0.25 to 0.30 total.
Recovery: 88 per cent. average.
Ratio of concentration: 20 or 21:1.
Labor: 46.2 tons per man per shift, operating; 241 tons per man per shift on repairs.
Water consumption: 2.8 tons per ton of ore milled; 66.5 per cent. re-used.
Power consumption: 15.8 hp.-hr. per ton milled.
General: Mill at mine. Water transported from 2 to 7 miles from wells. Railroad, ½ mile from mill. Power transmitted ½ mile. Concentrate shipped 1 mile. Gently sloping mill site.

Summary. Crushing: Gyratory from 12- in. to 2.5-in.; 2-stage roll crushing with second roll in closed circuit, 2.5- to 1.5-in. and 1.5- to 0.62-in.; 3-stage ball milling to 48-mesh. Concentration: All-flotation, rougher-cleaner routing. Primary flotation at 10 to 15 per cent. +48-mesh; slime from primary tailing re-floated in secondary machines, sands re-ground and returned to the primary machines.

Notes to Fig. 55.

Numbers in parentheses indicate tons solid per 24 hr., those in brackets, tons water per 24 hr. *a*, There is some difference between the different sections. *b*, See Sec. 23, Art. 3. *c*, Because of small storage capacity the coarse-crushing plant must be operated 24 hr. Hence two complete units like the preceding are maintained, although only one is in use at any time. *d*, Throw at discharge, 1-in.; 50-hp. motor, 22 hp. consumed. Spindle speed, 118 r.p.m. Oil consumption, 0.35 qt. per shift. Life of eccentric bushings, 30 days. Manganese-steel concaves last 100 days; about 8 hr. required for a change. *e*, 50-hp. motor, 125 r.p.m. Shells, Midvale steel, 5 in. thick when new and 2 to 3 in. when discarded. Bearings re-babbitted every 45 days, average. *f*, 200-hp. motor, 126 r.p.m. Shells, Midvale steel, 6½ in. thick new, wear to 2 in. in 45 days, when they are discarded. Manganese-steel cheek plates last 7 days. Bearings re-babbitted every 45 days, average. Eight

Al_2O_3	15.5	7.7

Summary. CRUSHING: Jaw crusher, 10- to 2-in.; [illegible] slow-speed geared rolls in closed circuit with shaking screens, 2- to 0.12-in.; tube mills, open-circuit, from 0.12-in. to 60-mesh. CONCENTRATING: All-flotation, com[illegible]nation roughing. Concentrate handling is peculiar in that no thickener is used ahead of the filter. Bucket elevators are used throughout for lifting pulp. This is old-style and less satisfactory practice on fine sands and slimes than the usual American practice with centrifugal pumps.

a, [illegible] 16-ton hopper cars with [illegible] locomotive. *b*, [illegible] lined with [illegible] manganese-steel jaw plates. [illegible] *c*, Water spray [illegible] ft. long, [illegible] 275 ft. per min. [illegible] is scraped off into a launder at start of return run. [illegible] round-hole punched plate, 14 or 16 gage. [illegible] of ¼-in. plate. [illegible] @ 1½-in. strokes per min. *f*, 25 per cent. moisture. *g*, 24 r.p.m. [illegible] ged roll belt-driven, plain roll gear-driven. Life of chrome-steel [illegible] tons. *h*, [illegible] annular opening. *i*, [illegible] per cent. moisture. *j*, −[illegible]-mesh. *k*, [illegible] type. [illegible] r.p.m. Each gear-driven by [illegible]-hp. [illegible] rings on both rotor and counter shaft. [illegible] mechanical performance. Mills are run in [illegible] and liners. Life of ribbed cast-iron shell liners 25,000 tons [illegible]

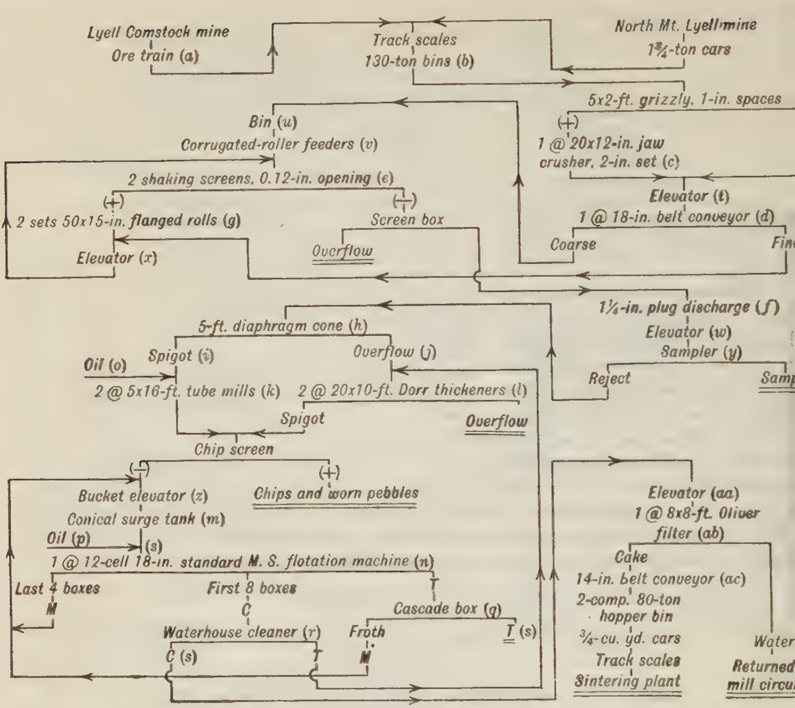

FIG. 56.—Mt. Lyell M. and M. Co.

sumption Tasmanian quartzite pebbles (2½- to 4-in. diam.). 11 lb. per ton. *l*, 8 min per rev. Spigot product, 40 per cent. solid. Tanks, 3/16-in. plate on sides and ¼-in. on bottom. Gravity discharge through 4-in. gate valve. *m*, 2½-ft. diam. × 3½ ft. deep. *n*, Cast-iron liners. 4-bladed impellers, 19-in. diam., 320 r.p.m., ¼-turn belt drive, 2-in impeller shafts, S. K. F. radial and thrust ball races. 4-in. ball-bearing line shaft. 75-hp motor, 14-in. camel-hair belt. 2-bladed froth skimmers, 19 r.p.m. Air added under first impeller. 18 per cent. solids in feed. Temperature varies from 47° F. in winter to 74° in summer. Operations are best at the higher temperatures. *o*, Mixture: one part eucalyptus oil and two parts coal tar by disk feeder; eucalyptus oil separately by pet cock. *p*, As needed. *q*, See Fig. 57. *r*, Not used regularly on account of excessive water consumption. Consists of box containing concentrate, into which high-pressure (80 lb.) water is passed by a jet ejector (3/16-in.) *s*, For sizing analysis see Table 42. *t*, 33¼-ft centers, 75° slope; 12-in., 8-ply balata belt; 12 × 6 × 5-in. buckets spaced 15 in. 380 ft per min. *u*, 2 @ 150 tons each. 45° bottom slope. *v*, 20 × 20 in. 2 r.p.m. *w*, 35½-ft centers, 80° slope, 12-in. @ 8-ply balata belt; 12 × 6 × 5-in. buckets spaced 9 in. 41 ft. per min. *x*, 25¾-ft centers, 80° slope, 12-in. @ 8-ply balata belt; 12 × 6 × 5-in. buckets spaced 9 in. 367 ft. per min. *y*, Double-cone type. Cuts 1 part in 3280. *z*, 27½-ft centers, 80° slope, 12-in. @ 8-ply balata belt; 12 × 6 × 5-in. buckets spaced 9 in. 35 ft. per min. *aa*, 40¼-ft. centers, 80° slope, 12-in. @ 8-ply balata belt; 12 × 6 × 5-in buckets spaced 24 in. 367 ft. per min. *ab*, 1 rev. in 8 min. Dry-vacuum pump, 3½ (diam.) × 8-in. 250 r.p.m. 22-in. vacuum. Feed contains 52 per cent. moisture and cake 11.5 per cent. Cake thickness, ¼ to 2 in. Capacity about 600 lb. solid per sq. ft. per 24 hr. Drum winding, 14-gage copper-clad steel wire, turns spaced ⅝ in. Life of canvas about 8 mo., 16 hr. required to re-cover and re-wind. Pneumatic agitation unsatisfactory. Filter replaced 3 @ 30 × 8-ft. steel draining tanks with filter bottom, connected with wet-vacuum pump. Concentrate drained therein to 15 per cent. moisture in one week. **ac, 50½-ft. centers, +26° slope, 137 ft. per min. 4-ply belt.**

Utah Leasing Co. Fig. 58. *(Q; 20 S. L. Min. Rev. 21; 105 J 535.)*

Location: Newhouse, Utah.

Ore: Dump tailing from Cactus mill of So. Utah Mines and Smelters. Chalcopyrite in quartzite gangue. Average copper content, 0.70 per cent., of which 0.10 per cent. is oxidized in sandy material and as much as 0.30 per cent. in slimes. Oxidation is greatest in dry, shallow parts of dump. For sizing tests of sand and slime portions see Table 43.

Capacity: 700 tons per 24 hr.

Assays, per cent. Cu (Sept., 1918): Feed, 0.584; concentrate, 16.85; tailing, 0.202. Concentrate contains about 2.5 oz. silver and 0.09 oz. gold per ton.

Recovery: (Aver. 1918) 62 to 65 per cent.

Ratio of concentration: Aver. 40 : 1.

Percentage possible running time: 92 (aver. 3½ years).

Labor: 104 tons per man-shift, operating; 310 tons per man-shift, repairs.

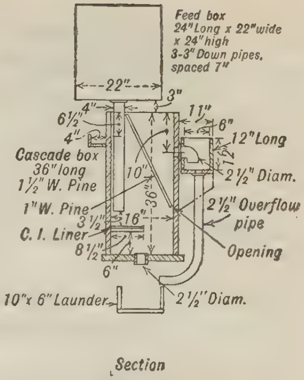

Fig. 57.—Cascade-type tailing-retreatment box, Mt. Lyell mill.

Power: 17 hp.-hr. per ton milled. Motors 5- to 20-hp., 440-volt; over 20-hp., 2200-volt.

Water: 750 gal. per ton of ore milled.

General: Dump material excavated with 30-ton steam shovel (a drag-line scraper failed) and hauled an average distance of 600 ft. to mill by dinky train. Cost per ton (1917), $0.12. Concentrate shipped 220 miles.

Summary. One-stage ball and pebble milling (mills in parallel) followed by agitation-froth flotation, concentrate-middling routing.

This is a typical, cheap dump-tailing flotation plant. Cost of such plants per ton of daily capacity is extremely low. (See Sec. 23, Table 37.)

b, Belt-driven. Satisfactory. *c,* See Sec. 4, Table 11. *d,* 24 @ 12-in. strokes per min. Slope, 2⅞ in. per ft. 5-hp. motor. Overflow, 27 per cent. solid. Total load, 600 tons per 24 hr. Life of submerged rakes, 18 mo.; balance, 3 yr. *e,* For sizing test see Sec. 4, Table 11*a*. *g,* 23 @ 10-in. strokes per min. Slope, 2½ in. per ft. 3-hp. motors. Overflow, 27 per cent. solid. Total load, 400 tons per 24 hr. Life of rakes as above (*d*). *i,* 2 @ 22 × 10 ft., 1 @ 50 × 10 ft. Spigot products held at 55 to 60 per cent. moisture because elevator will not handle thicker material. *j,* Feed, 15 to 20 tons per 24 hr. all −65-mesh. Cake contains 18 to 22 per cent. water; as high as 26 per cent. in winter. Gage reading, 18 to 20 in. mercury. Speed, 1 rev. in 18 min. *k,* Cost (1917), $0.0805 per ton. Combined grinding cost (1917), $0.205 per ton. *m,* Cost of concentrate handling (1917), $1.26 per ton of concentrate or $0.0347 per ton of ore milled.

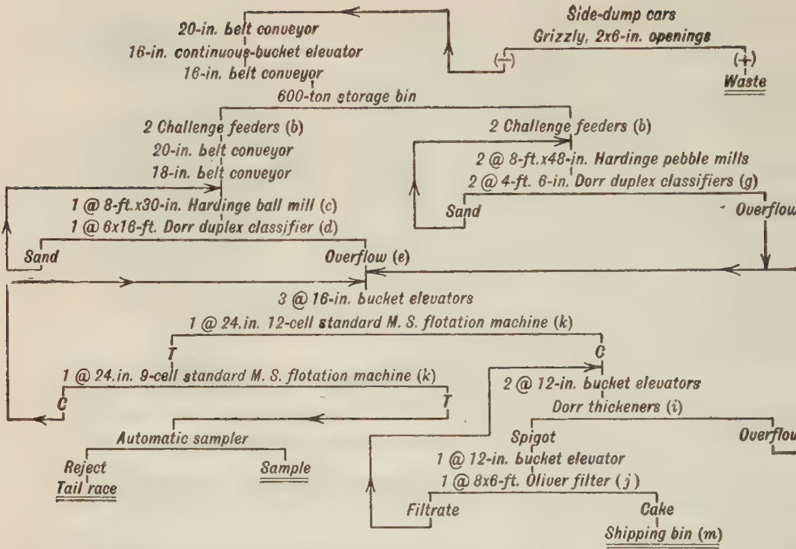

FIG. 58.—Utah Leasing Co.

Braden Copper Co. Fig. 59. (*Q; 101 J 315; 28 IMM 236.*)

Location: Sewell, Chile, S. A.

Ore: Chalcopyrite (75 per cent. of total copper), bornite and chalcocite in shattere andesite. Variable proportions of copper oxides, carbonates and silicates.

Capacity: 10,000 tons per 24 hr.

Assays, per cent. Cu: Feed, 2.0 to 2.3; concentrate, 18 to 20; tailing, 0.4 to 0.45.

Recovery: 80 to 82 per cent.

Ratio of concentration: 10 : 1.

Labor: 12 tons milled per man-day.

Power: 24.7 kw.-hr. per ton milled.

Water: 3.2 tons net per ton of ore.

General: Mill is about 1¼ miles from mine. Smelter on property. Power transmitte 18 miles at 33,000 volts. Ore hauled by electric railroad. Fall from top of coarse-ore bir to bottom of filter plant is 400 ft.

Summary. CRUSHING: Gyratory from 12- or 14- to 3-in.; disk crushers an rolls (in parallel) from 3- to 1-in.; ball mills from 1- to 0.16-in.; 2-stage ba milling with intermediate sizing, classification and table concentration t 40-mesh flotation size. CONCENTRATION: Shaking tables followed by flota tion of primary slimes and re-ground table tailing. Roughing-cleanin routing.

This mill replaced a smaller up-to-date gravity-concentration plan having jigs, tables and buddles, in which average recovery was only abou 50 per cent.

Notes to Fig. 59.

Table 48. Water supply at Inspiration (May, 1925)

	Gallons per ton of ore	Tons per ton of ore	Per cent. of reclaimed water	Per cent. of total water
Reclaimed water				
Tanks	494.3	2.061	78.8	54.5
Ponds	132.8	0.554	21.2	14.6
Total	627.1	2.615	100.0	69.1
Fresh water	279.4	1.165	....	30.9
Total water	906.5	3.780	....	100.0

General: Mill has 20 units. For arrangement of machines see Figs. 62 and 63.

Flotation agents: Potassium xanthate (Z–30), 0.2435 lb; pine oil, 0.1513 lb.; lime, 1.216 lb. per ton.

Summary. One-stage ball milling from 3-in. to −35-mesh. Flotation by rougher-cleaner routing followed by tabling of de-slimed flotation tailing

Consolidated Coppermines Co., Fig. 64. *(64 A 816.)*

Location: Kimberley, Nev.

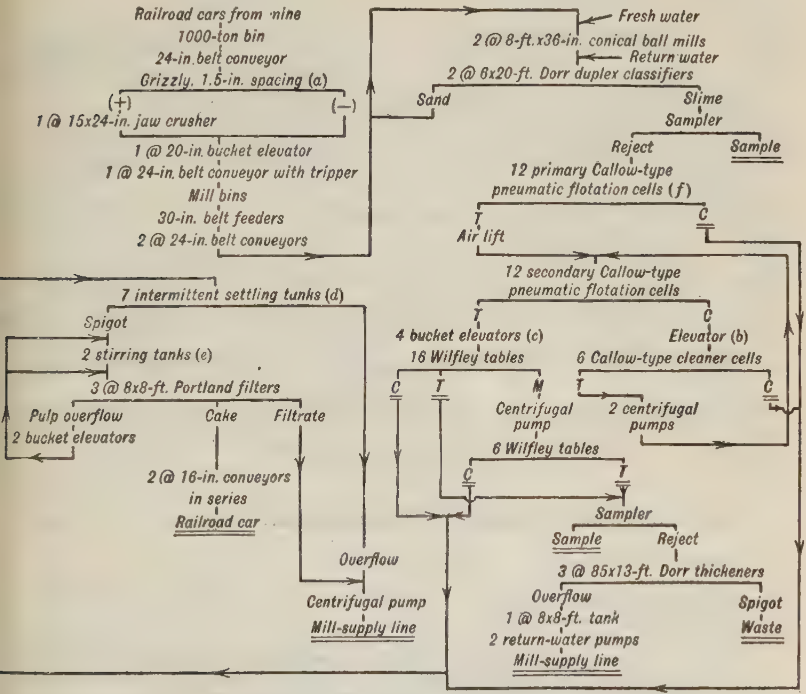
Ore: Typical porphyry copper ore containing chalcocite and some pyrite. Analysis: Cu, 1.4 per cent.; SiO_2, 64 to 85 per cent.; Al_2O_3, 4 to 12 per cent.; Fe, 4 to 5 per cent.; CaO, 0.5 to 2.5 per cent.; S, 2.7 to 3.2 per cent.; Au, 0.01 to 0.02 oz.; Ag, 0.05 to 0.08 oz.

Capacity: 1000 tons per 24 hr.

Assays: Feed, see above; concentrate, see Table 49.

Recovery: See Table 49.

Ratio of concentration: See Table 49.



a, 2 × 12 ft. *b*, Diaphragm pump in one section, bucket elevator in the other. *c*, In sets of 2. *d*, 6 @ 20 × 8-ft. Goldfield tanks and 1 @ 30 × 6-ft. 6-in. settling tank, in parallel. *e*, 20 × 8-ft., Goldfield type. *f*, Flotation agents were various mixtures of coal tar and pine oil from the start (May, 1917) to Aug., 1918; thereafter X–Y mixture (alpha- and beta-naphthylamine and xylidin), all in alkaline circuit with lime. For comparison of results see Table 49. Note the increase in recovery and grade of concentrate caused by the X–Y reagent. There was a corresponding reduction from 17.2 to 9.4 per cent. in the moisture content of filter cake. Savings were: smaller tonnage of concentrate to be filtered, freighted and smelted; quicker filtration (one shift with 1 or 2 filters against 3 shifts with 3 filters).

Fig. 64.—Consolidated Coppermines mill.

Summary. Crushing: Jaw crusher, 12- to 2-in.; one-stage closed-circuit ball milling to flotation size. Concentration: Pneumatic flotation, combination routing, with shaking-table treatment of flotation tailing without classification. Concentrate thickened in intermittent settling tanks.

a Pensacola No. 80.

Phelps Dodge Corp. Copper Queen concentrator. Fig. 65. (*111 J 1079.*

Location: Bisbee, Ariz.
Ore: Porphyry.
Capacity: 4800 tons per 24 hr.
Assay: Feed, 1.5 per cent. Cu.
Recovery: 90 per cent.
Power: From smelter at Douglas. 6000 hp. Diesel auxiliary plant at mill.
Water: Total re uirement, 1516 gal. per ton. Of this 1140 gal. per ton is reclaimed the Dorr tanks and filters. Fresh water from mine, about ⅔ mile distant.
General: Sloping millsite. Building, steel with corrugated-iron siding and compositio roofing. Dorr tanks and flotation cells of concrete.

Summary. Crushing: Jaw crusher, 60- to 8-in.; gyratory, 8- to 4-in disk crushers, 4- to 1.25-in.; 2-stage rod-milling to 14- and 48-mesh, respectively, first stage open-circuit. Concentration: Shaking tables preceding and following pneumatic flotation, rougher-cleaner routing.

Notes to Fig. 65.

a, 335 ft. long. *b,* 150-hp. motor each. Rod charge, 36,000 lb. 3-in. high-carbon steel rods. 17½ r.p.m. Crushing to 14-mesh, single pass. *c,* Concrete, 22-compartment, 231 sq. ft. blanket area, each machine. *d,* Concrete, 6-compartment, 83 sq. ft. blanket area, each machine. *e,* Feed, 38.5 tons each. 1-hp. individual motors. *f,* F the 4 units. *g,* All conveyors have ball-bearing troughing and return idlers. Automat electrical interlock with crusher drives to prevent damage from stoppage of any machin

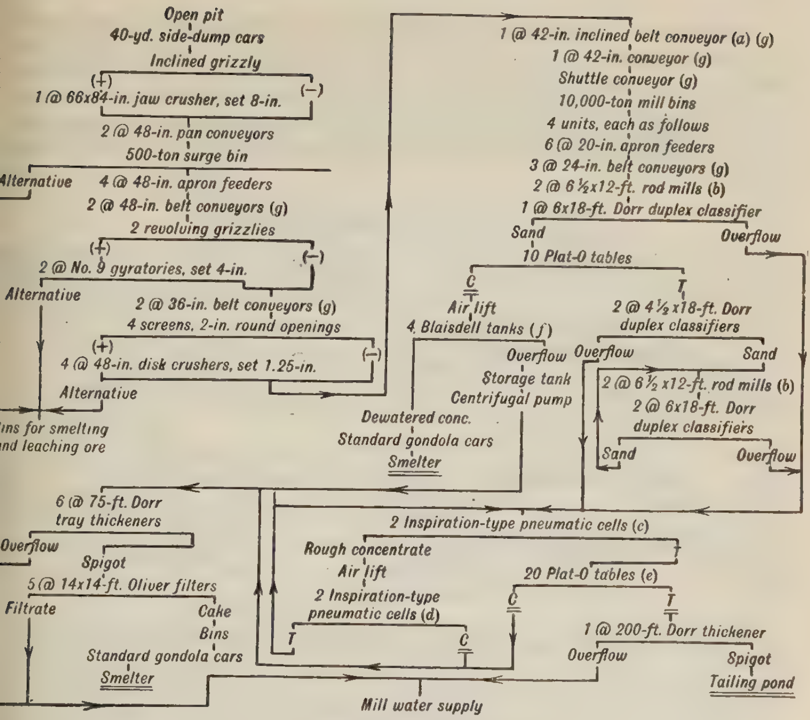

FIG. 65.—Copper Queen concentrator.

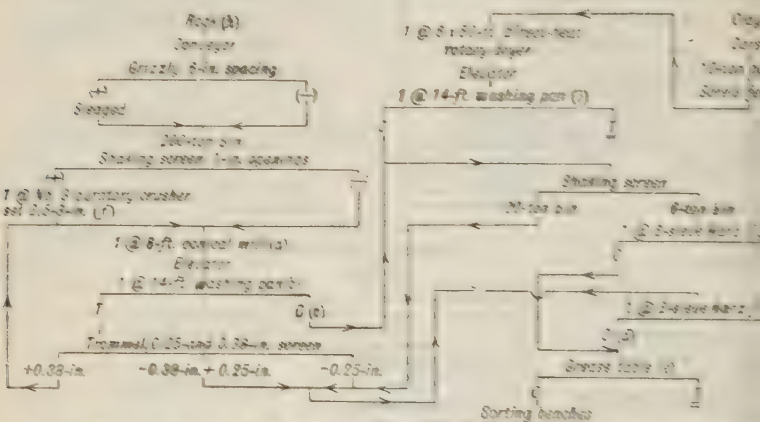
15. Diamond (C)

Properties. Diamonds are a crystalline form of carbon. They occur in two forms, *viz.*: the crystalline or gem variety and the amorphous-appearing variety, known as CARBON or CARBONADO. SPECIFIC GRAVITY of gem diamonds is 3.50 to 3.56; LUSTER of cleavage faces is adamantine, while the natural faces have a more greasy luster. SPECIFIC GRAVITY of carbonado ranges from 2.75 to 3.42 and the LUSTER is dull and earthy.

Uses. The principal use of the crystalline variety is, of course, as a gem stone. Chips and dust from cutting the gem varieties are used as polishing powder for gem diamonds and for other gems. BORT, a low-grade crystalline form, and carbonados are used as abrasive cutters, dies, and pivot bearings in delicate apparatus. The best carbons are used principally for setting diamond-drill bits. Poorer grades are used to point cutting tools in turning machines, glass cutters, and the like.

Ores. Until about 1870, the sources of gem diamonds were placer deposits, the principal ones being in India and Brazil. Since 1870, the South African mines (KIMBERLEY, JAGERSFONTEIN, PREMIER, etc.) have supplied the bulk of the world production. Here the diamonds occur scattered through an altered peridotite (blue ground). A somewhat similar occurrence is found near Murfreesboro, in Pike County, Ark., but while a considerable number of diamonds has been found in this deposit, it has not been proved up or worked on a commercial scale. Carbonados are found in only one locality, *viz.*: the highlands of the state of Bahia, Brazil. The deposits are in patches in quartzites and in river gravels derived from these rocks.

Production. The potential production of gem diamonds in South Afri[ca] exceeds the world demand, and, in order to maintain prices, the actual pr[o-]duction is closely limited by government officials working with the min[ing] companies. The demand for carbonados, on the other hand, is in exce[ss] of the supply with the result that prices (1924) ranged from \$90 or \$100 p[er] carat for the poorer and smaller stones to \$150 or even higher for choi[ce] stones.



a. No grinding medium. The larger lumps of hard rock are depended upon to eff[ect] disintegration. Fine grinding is not desired. b. See Sec. 8, Art. [illegible] c. 1 to 2 per ce[nt] of the original tonnage. d. [illegible] per cent of jig feed [illegible] per cent [illegible] This material consists of diamonds together with all heavy minerals from the rock. [In] South Africa these are pyrope, zircon, [illegible] chrome [illegible] pyroxene, [illegible] ilmenite, magnetite, chromite, [illegible] barite, [illegible] and pyrite. [illegible] Sec. [illegible] e. Will recover stones as small as [illegible] to the carat. Originally gravity concentrates were hand-picked to recover the diamonds. [illegible] weathering has been displaced on account of the cost of handling, [illegible] large amount of capital tied up in the weathering material. h. The following [illegible] may be taken as illustrative of South African practice. i. Frequently not [illegible] South African mills.

Drying and subsequent wetting as practiced on the clayey rock cause the clay to sl[ake] down to a thin mud, while without drying it is extremely difficult to disintegrate. T[his] treatment is a local development, not typical of South African practice.

Fig. 66.—Arkansas Diamond Corporation.

Treatment depends upon the kind of ore and the locality. The carbona[do] gravel deposits are worked by the Brazilian natives in bateas or, in the m[ore] elaborate plants, in sluices, sluice concentrate being worked up in the bat[eas.] A native with a batea can work about 1 cu. yd. of gravel per day when [it] is easily accessible, uncemented and near water [illegible]. The So[uth] African blue-ground deposits are treated in concentrating mills in which [the] general method of treatment is careful disintegration (formerly by weather[ing] for 3 or 4 months to two years, but recently by mechanical means), conce[n-]tration by washing in rotary pans, sizing of the concentrate, jigging, treatme[nt] of jig concentrate on greased shaking tables or greased-belt vanners, clean[ing] the concentrate by melting and pouring off the grease and washing the s[...] residue with hot caustic solutions and with hydrofluoric acid, and fin[ally] hand sorting and grading the ultimate concentrate [illegible]. The flow-sh[eet] of the Arkansas Diamond Corp. shows a recent mill scheme.

Arkansas Diamond Corp. Fig. 66. (*109 J 983.*)

Location: Murfreesboro, Ark.
Ore: Peridotite in place and residual clays resulting from weathering.
Capacity: 20 to 25 tons per hr.

Summary. Careful disintegration to free the diamonds without breaking them, followed by gravity concentration and re-treatment of gravity concentrate on greased tables.

16. Emery and Corundum

Properties. Corundum (Al_2O_3) occurs as the gem varieties, SAPPHIRE and RUBY; as a dull to dark, non-transparent crystalline variety, called CORUNDUM; and as a black or grayish-black granular variety, intimately associated with hematite and magnetite, called EMERY. HARDNESS, 9; SP. GR., 3.9 to 4.1.

Uses. The massive crystalline corundum and the granular emery are used in the form of wheels, bricks, coated papers, grains and powders as abrasives in metal and stone polishing, and as knife-edges and jewel bearings in delicate apparatus. As abrasives they come into competition with the artificial abrasives (carborundum and alundum) and, due to the fact that the latter are more uniform and reliable they have largely displaced the natural minerals.

Ores. Corundum occurs as loose fragments and crystals in residual soils; as placer deposits, and as a constituent of crystalline rocks, *e.g.*, pegmatites, gneisses, granites, schists and the like and also in crystalline limestones. Emery occurs in similar crystalline rocks. The principal corundum deposits of the world are in a region in the Transvaal where known deposits of all three varieties are scattered over 2000 square miles. (*So. Afr. Jour. Ind., Dec., 1924.*) There are also large deposits of both gem and crystalline corundum in India. Canada has important deposits. The most important emery deposits are in Greece. There are workable deposits in New York, Massachusetts and Virginia.

Production of corundum in Canada was about 1200 tons in 1913 and 400 tons in 1921; in India 400 tons in 1913, 2100 in 1917 and 200 in 1920; in South Africa, 13 tons in 1913, 3900 in 1918, and 600 in 1921. Production of emery in Greece in 1912 was 7900 tons and in 1921, 11,000 tons. Domestic production of emery was 1000 tons in 1913; 17,000 tons in 1917; 300 tons in 1921, and 2000 in 1924. The great expansion in 1917 was due to interruption with the Greek supply.

Selling. The value of corundum and emery depends on their hardness and toughness. The best grades are those tough enough not to crumble readily, but which crumble sufficiently at the surface, under ordinary grinding pressures, to present ever new, rough abrasive surfaces. There are no standards. Chemical analysis is indicative, but appearance and the behavior of sample lots are the final test. Both corundum and emery are marketed in crude lump form and finished by crushing and extremely close sizing in the plants of the abrasives manufacturers. The South African corundum output has ranged in value, from 1919 to 1924, inclusive, between \$30 and \$40 per ton. Exports of two tons of Canadian corundum in 1924 were valued at \$125 per ton. Domestic emery production since 1919 has ranged in value from about \$7.50 per ton in 1921 to \$12.75 per ton in 1923. (*33 MI 1.*) Best-grade imported (Greek and Turkish) emery was quoted (*J, Feb. 6, 1926*) at 6½ cents per lb.

Treatment. Residual and placer ores are treated by simple washing processes. The crystalline ores are treated by gravity concentration. THE MANUFACTURERS CORUNDUM Co. mill (Fig. 67), burned in 1913, was probably the most elaborate of such plants.

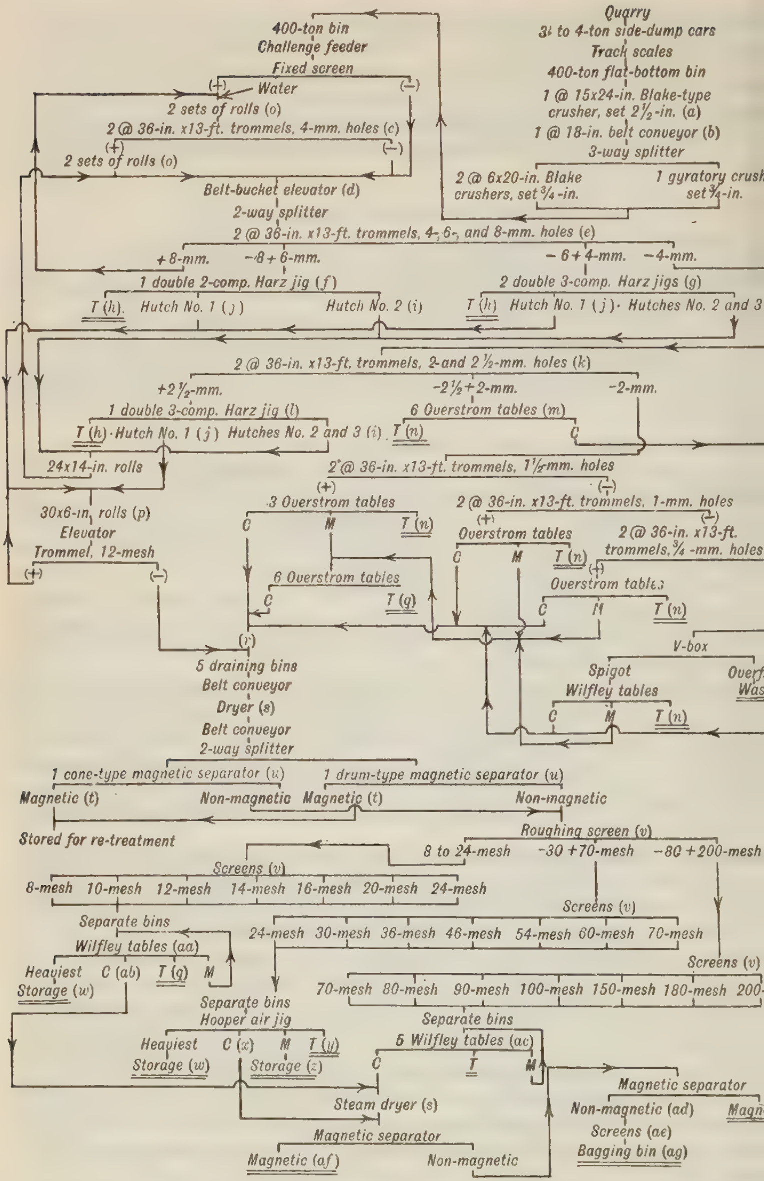


FIG. 67.—Manufacturer's Corundum Co.

a, 250 r.p.m. *b,* 85 ft. long, 20 per cent. grade. 300 ft. per min. *c,* 20 r.p.m.; sl 1 in. per ft. *d,* 18 × 6 × 6-in. buckets; 350 ft. per min. *e,* 20 r.p.m.; slope, 1 in. per rope drive. 6 ft. of 4-mm. screen, 4 ft. of 6-mm. screen, 1½ ft. of 8-mm. screen. *f,* 2

36-in. sieves with 6-mm. holes. 170 @ 1-in. strokes per min. Bedded with oversize corundum. *g*, 24 × 36-in. sieves with 8-mm. holes, 200 @ ⅞-in. strokes per min. Bedded with coarse corundum. *h*, About 3 per cent. corundum. Jigs overloaded. *i*, 35 to 45 per cent. corundum. *j*, About 50 per cent. corundum. *k*, 6 ft. of 2-mm. screen, 5 ft. of 2½-mm. screen. Speed and slope as in note (*e*). *l*, 24 × 36-in. sieves. 4-mm. holes. Bedded with coarse corundum. *m*, Feed is too coarse. *n*, 2 per cent. corundum. *o*, 40 × 14 in. *p*, Set to crush to 12-mesh. *q*, 5 per cent. corundum. *r*, 50 per cent. corundum. *s*, Two-deck, steam, 1¼-in. pipes under 4-mesh screen. Dry material drops through the screen and between the pipes onto a conveyor belt. *t*, 4 to 5 per cent. corundum. *u*, Feed contains 12 to 15 per cent. magnetic iron. *v*, Steel-wire screen from 8- to 30-mesh; silk cloth for finer sizes. *w*, Magnetite and pyrite. Stored outside for possible future treatment. *x*, 90 to 95 per cent. corundum. *y*, 4 to 6 per cent. corundum. *z*, Held until enough accumulates for re-treatment on the air jig. *aa*, 215 @ ¾-in. strokes per min. Different sizes treated separately. *ab*, 88 to 90 per cent. corundum. *ac*, 250 @ ⅜-in. strokes per min. Different sizes treated separately. *ad*, Contains 1 to 2½ per cent. combined iron. *ae*, Finishing screens to guard the preceding sizing. *af*, Coarse sizes, 7 per cent. corundum; fine, 3 per cent. *ag*, Sacked in 100-lb. bags. Three grades made for wheel-making; highest 90 to 95 per cent. pure.

Manufacturers Corundum Co. Fig. 67. (*Mem. 57, Canada Dept. of Mines, 300.*)

Location: Craigmont, Ont., Canada.
Ore: Corundum syenite.
Capacity: 150 tons per 24 hr.
Assays, per cent. corundum: Feed, 10 to 12; concentrate, 90 to 95 ; tailing, 5.
Recovery: 58 per cent.
Cost (1913) including mining, selling and all overhead was about $40 per ton shipped.

Summary. Graded CRUSHING from 10- or 12-in. to 8-mm. by two steps in crushers and two steps in rolls. Preliminary CONCENTRATION by jigs and tables, following close sizing. Final concentration of very closely-sized fine products by pneumatic jigs, shaking tables and magnetic separators. Note that the extremely close sizing preceding this final concentration is on account of the sizing demanded in the finished product; it is certainly unjustifiable from a concentrating standpoint.

17. Fluorspar

Properties. Fluorite, CaF_2, is a cleavable, light-colored, transparent to translucent mineral; SP. GR., 3 to 3.2; HARDNESS, 4. It decrepitates when heated to about 1200° F.

Uses. The principal consumption (80 to 85 per cent.) is as a flux in the basic open-hearth process of steel making. The balance is used in the ceramic industries, as a flux to increase fluidity of slags in copper blast furnaces, and in iron- and brass-melting furnaces; as a source of hydrofluoric acid and sodium fluoride; in making emery wheels and carbon electrodes; and in the extraction of potash from feldspar and cement-mill flue dusts. A small amount is used for optical lenses (*32 MI 247*).

Ores. Fluorspar occurs frequently as a gangue in lead-zinc ores, associated with calcite. It also occurs in veins in gneiss, slate, sandstone and limestone.

Production in the United States has ranged from 138,000 tons in 1919, 187,000 in 1920, and 35,000 in 1921 to 125,000 in 1924 (*USGS*); about 60 per cent. comes from Illinois and 35 per cent. from Kentucky. Imports have ranged in the same time from 6000 tons to 42,000 tons, Great Britain supplying about half of the tonnage.

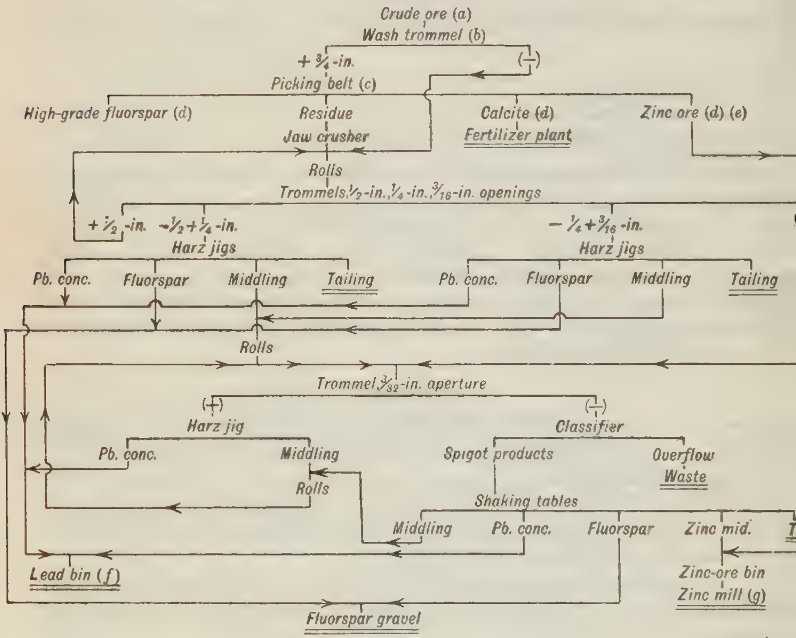
Selling. The market grades are lump, gravel and ground. The general silica limit for lump and gravel is 6 per cent; for the ceramic industry, 3 to 5 per cent.; for hydrofluoric acid, 1 per cent. For metallurgical purposes the standard specifications set 85 per cent. minimum CaF_2 and 5 per cent. maximum silica. Lead and zinc are objectionable in ceramic manufacture and calcium carbonate in acid manufacture. PRICES ranged from $25.50 per ton average

in 1919 to \$19.60 in 1924 with a low of \$17.80 in 1922. The quotations f.o.b. Kentucky and Illinois mines (*J, Feb. 6, 1926*) were \$17.50 per ton for gravel not less than 85 per cent. CaF_2 nor more than 5 per cent. SiO_2; \$20 for lump of the same purity; \$32.50 for material ground to substantially 100-mesh, 95 to 98 per cent. CaF_2 and not over 2½ per cent. SiO_2. Ground acid stock in bags, \$40 to \$45.

Treatment varies according to the character of the ore. In the Kentucky ores the waste is principally clay and sand and concentration is done by log washers. In the Illinois field the two largest mines are vein deposits with galena and sphalerite in a gangue of fluorspar and calcite.

Fairview Fluorspar and Lead Co. (Fig. 68) at Rosiview, Ill., is typical (*111 J 222.*)

Summary. Picking, graded crushing, sizing and classification followed by jigs and shaking tables.



a, Contains 10 to 30 per cent. waste. *b*, Part blank plate, part ¾-in. round-hole plate. *c*, About 50 ft. long, 24 in. wide, 25 to 40 ft. per min. *d*, Picked. *e*, Finely disseminated. *f*, Concentrate, 75 to 80 per cent. Pb and 7 to 8 oz. Ag per ton, amounting to 1 to 2 per cent. of the crude ore hoisted. *g*, Flotation is probably the best method of treatment, although electrostatic concentration has been tried.

Fig. 68.—Fairview Fluorspar and Lead Co.

At the Rock Candy mill, at Trail, B. C., the fluorite occurs in a silicious gangue and separation is made by crushing to about ½-in., sizing on ¼-in., 8-mesh and 15-mesh screens, heating the oversize products to about 1200° F. to cause decrepitation of the fluorite and then concentrating by re-screening. (*Ladoo.*)

18. Garnet

Properties. Garnet is a generic term covering several species of tri-silicates, viz.: grossularite, $Ca_3Al_2(SiO_4)_3$; pyrope, $Mg_3Al_2(SiO_4)_3$; almandite, $Fe_3Al_2(SiO_4)_3$; spessartite, $Mn_3Al_2(SiO_4)_3$, all known as aluminum garnets; iron garnet, andradite, $Ca_3Fe_2(SiO_4)_3$, and chrome garnet, uvarovite, $Ca_3Cr_2(SiO_4)_3$. All species have similar physical properties and crystal form. LUSTER is vitreous. SP. GR., 3.5 to 4.3. PERMEABILITY, see Sec. 13, Table 2. The important properties from an economic standpoint are the HARDNESS, varying from 6 to 7.5 in the different varieties, and TOUGHNESS.

Uses. Garnet has been used as a gem for a long time, but production for this purpose is small and relatively unimportant. A small amount of foreign garnet is used for watch jewels. The principal use is as an abrasive, both in loose form and mounted on paper and on cloth backing.

Ores. The most important garnet is almandite, which has a sp. gr. from 3.9 to 4.2, and hardness from 7 to 7.5. The color varies from red to black. The usual occurrence is in granitic and metamorphic rocks, such as schists, gneisses and crystalline limestones, associated with quartz, micas, feldspars, pyroxenes and hornblendes. Corundum, rutile, magnetite, pyrite, pyrrhotite and chalcopyrite are also common accessory minerals. For economical operation, the ore should ordinarily contain upwards of 6 per cent. garnet; some ores contain as high as 60 per cent., but 10 to 15 per cent. is the usual maximum. While garnet deposits are common in all parts of the world, yet with the above limitations, and the further requirement as to suitable hardness and toughness for abrasive service, the number of deposits of sufficient richness and so located as to repay exploitation are relatively few. This fact, coupled with the difficulty of concentration and the relatively small demand for the finished product has resulted in a virtual monopoly of the domestic industry in the hands of a few companies.

Production of abrasive garnet in the United States was 5000 tons in 1919, 3000 in 1921, 9000 in 1923 and 8000 in 1924. (*U.S.G.S.*) About half of this comes from the NORTH RIVER GARNET CO. and about 1000 tons from the BARTON MINES CORP. Canada is the most important foreign producer (1250 tons in 1924). Small amounts come from Japan, Spain and India (*33 MI 6*).

Selling. Unsized garnet concentrate (—2-in., assaying about 90 per cent. garnet) is shipped in 100-lb. sacks to the abrasive manufacturers who crush and grade it closely into 12 to 16 sizes, as per Table 56.

PRICES of domestic grades since 1920 have ranged from \$75 to \$85 per ton of unsized concentrate. Canadian is quoted \$5 to \$15 per ton cheaper f.o.b. mines and Spanish \$20 to \$25 cheaper, c.i.f. port of entry.

Treatment. The large mills treat the crude ore by close sizing and classification followed by jigging and tabling, and at the plant of the NORTH RIVER GARNET CO. (Fig. 69) the fine concentrate is re-cleaned on pneumatic jigs. Some small plants use pneumatic concentration throughout (Fig. 70). Electrostatic and magnetic concentration have both been tried, but have not been successful.

North River Garnet Co. Fig. 69. (*118 J 525.*)

Location: Near North Creek, N. Y.

Ore: Almandite in gneiss composed principally of hornblende and feldspar. The garnet crystals range in size from about 4-in. diameter downward, but average about 0.5-in.

Capacity: 400 to 500 tons per 20 hr.

Ratio of concentration about 25 : 1.

Concentrate assay about 90 per cent. garnet.

Labor: 25 to 30 tons per man-shift, operating.

Table 50. Comparative sizes of abrasive grains (*a*). (*After Ladoo, U.S.B.M., Ser. 2347*)

a In this table the size of grain as related to screen mesh is indicated by the position of the dots between the horizontal lines. Thus, No. 2½ garnet is about 38 mesh.

Summary. Closely-graded crushing to 0.25-in. followed by rough jigging of unzised feed with rejection of tailing and step re-treatment of middling on other water jigs and pneumatic jigs after close sizing.

The mill is an old one and has developed slowly, under great difficulty in an isolated district, which facts go to explain the crude and inefficient handling methods and high labor requirement.

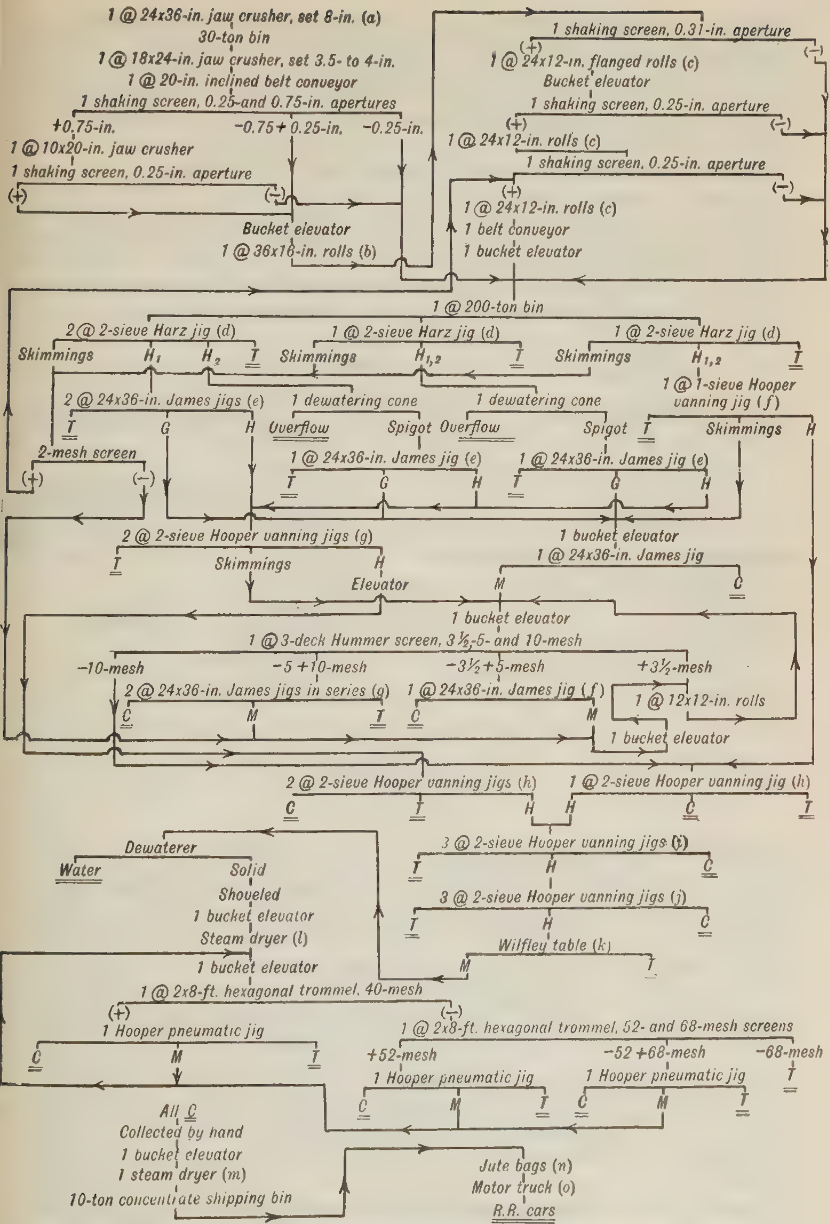

Fig. 69.—North River Garnet Co.

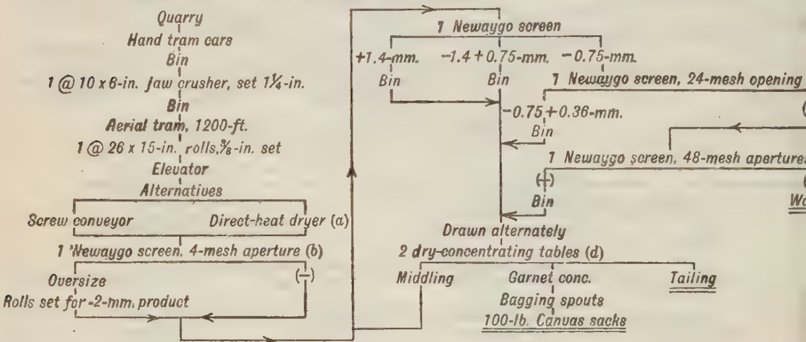
a, Hand-fed. *b*, Life of chrome-steel shells about 15 mo. *c*, Life of chrome-steel shells, 6 to 8 mo. *d*, 24 × 36-in. sieves, 0.25-in. and 0.19-in. screen on first and second

compartments, respectively. 200 @ 2-in. strokes per min. (wide) × 30 ft., inclined slightly more than angle of repose of sand. Bottom is 2 sets of 10 steam pipes. *n*, 130 to 135 lb. gross. Returned by consignee. *o*, 10 miles to North Creek.

Wausau Abrasive Co. Fig. 70. *(256 Bul. USBM 23.)*

Location: North Wilmot, N. Y.
Capacity: 50 tons of concentrate per week when running one 10-hr. shift per day.
Ore: Almandite crystals ¼- to ⅜-in. diameter constituting 40 to 60 per cent. of the rock. Feldspar and biotite the principal associates.

Summary. Graded crushing in jaw crushers and rolls; close sizing followed by pneumatic concentration. Fines (−48-mesh) wasted.



a Coal fired. *b*, −2-mm. undersize. *d*, Sutton, Steele and Steele.

Fig. 70.—Wausau Abrasive Co.

19. Gold and Silver

GOLD, Au

Properties. Metal; yellow, lustrous, soft, extremely malleable and ductile. See also Table 1. At. wgt., 197.2. Unchanged by air, water, dilute and concentrated acids at any temperature. Dissolves in the presence of free chlorine and of the soluble cyanides. Easily precipitated from its solutions by reducing agents. Uni- and tri-valent, both base- and acid-forming. Alloys freely with many metals, notably silver, copper, mercury and platinum.

Uses. The principal use is for coinage, for which purpose an alloy with copper is used. The composition of the standard coinage alloy in most countries is 900 parts gold and 100 parts copper (900 fine); Great Britain and Portugal, with standards 916.6 fine, are the principal exceptions. Jewelry is commonly manufactured from gold-copper alloys. The fineness of jewelry gold is expressed in carats. Pure gold, 1000 fine, is 24 carat. With this basic relation any other fineness or carat rating can be computed by simple proportion. Gold-silver alloys are used to some extent in jewelry manufacture, having a paler color than the usual alloys. An alloy of 750 parts gold and 250 parts iron is sometimes used by jewelers to make blue gold. A small amount of gold as leaf is used for gilding and gold lettering. Ruby-gold glass is a solid solution of colloidal gold in glass. Potassium aurocyanide is used in gold-plating by electrolysis. Certain gold salts are used in photography.

Ores. The economic minerals are native gold, calaverite and sylvanite. The principal ores are those containing native gold mechanically mixed with pyrite, less frequently with chalcopyrite, arsenopyrite, stibnite, sphalerite

and pyrrhotite, or with the oxidation products of these minerals or in the zones from which they have been leached. Native gold also occurs mechanically mixed with loose, water-sorted material (PLACERS). The metallic gold is almost invariably alloyed with more or less silver. The tellurides (sylvanite and calaverite) ordinarily occur associated with pyrite and with one or more of the other sulphides named above. Gold ores occur usually in fissure veins in sedimentary, igneous or metamorphic rocks or at contacts between any two of them. Hence the associated gangue minerals may be anything. The commonest gangue mineral is, undoubtedly, quartz.

Production. Gold in greater or less quantities is produced in more than 40 countries. World production for the years 1921 to 1924, inclusive (*USGS*) has ranged between 15,500,000 and 18,500,000 fine ounces per year. Of this more than one-half has come from the Transvaal, about 25 per cent. from North America, and about 15 per cent. of the total from the United States. California and Colorado account for about 50 per cent. of the domestic production.

Selling. Gold bullion containing less than 800 thousandths of base metal can be sold to United States assay offices in New York; Helena, Mont.; Seattle, Wash.; Deadwood, S. D., and Salt Lake City, Utah, and bullion of all degrees of fineness is bought by smelters. The amount paid by the government assay offices is the value of the fine gold at $20.67 per troy ounce less a charge to cover melting, parting, refining, etc. For a copy of the schedule and discussion of the sale of foreign gold see *Spurr and Wormser.*

SILVER, Ag

Properties. Metal; white, lustrous, soft, ductile. (See also Table 1.) AT. WGT., 107.88. Not attacked by air or water but becomes coated with a dark film of sulphide in air containing sulphuretted hydrogen. Not attacked by dilute acids, except nitric acid. Dissolves in hot concentrated sulphuric acid. Attacked slowly by hot concentrated hydrochloric acid, but a protecting layer of insoluble silver chloride quickly forms. Very resistant to basic substances even when these are in a fused state. Ion always basic, mono-valent. Alloys freely with most metals.

Uses. The principal use is as a component of an alloy for coins, jewelry and tableware. The chief alloys are those with aluminum, copper, zinc, nickel, and combinations of the same. Salts of silver are used to some extent in medicine and to a great extent in photography.

Ores. The economic minerals are metallic silver, argentite, argentiferous galena, cerargyrite, prousite, pyrargyrite, stephanite, tetrahedrite, polybasite. The most important ores are the silver-bearing lead ores in which the heavy mineral is principally argentiferous galena, usually associated with pyrite, sphalerite and rich silver-bearing minerals. The usual gangue minerals are quartz, calcite, barite and chert. The copper ores of Colorado, Utah, Montana and Arizona produce considerable silver. Silver is also usually associated with gold in both quartz-vein and placer types of deposit. Native silver and sulphides in quartz associated with a complex mixture of sulphides, arsenides, antimonides, etc., are important at Cobalt, Ont.

Production. World production is a fairly constant quantity, ranging, since 1893, between 5,000,000 and 7,900,000 kilograms (161,000,000 and 254,000,000 troy ounces) and averaging 5,900,000 kg. (190,000,000 oz.). Of this total, America produces 85 to 88 per cent.; Mexico, 37 to 39 per cent., and the United States, 25 to 30 per cent. The principal producing states, in order (1924), are, Utah, Montana, Nevada, Idaho, Arizona, California and Colorado.

Selling. Except in the case of the relatively small amounts of silver in gold bullion, most silver is sold by the mine in the form of a base-metal con-

trate and hence goes to the smelter. The net price paid by the smelter varies according to the particular contract, but usually 95 per cent. of the silver content of the concentrate is paid for at the New York price for bar silver at some particular time with respect to the date of delivery of the concentrate. The average price of silver varies considerably, as shown by Table 51. Much

of the apparent stability since 1920 has been due to large United States government purchases.

TREATMENT

The ores of gold and silver constitute an endless variety, but, from the point of view of milling they may be roughly classed as (1) placer deposits, (2) simple free-milling vein deposits, (3) simple sulphide ores, (4) complex or refractory ores in which the precious metals are the principal economic constituent, (5) complex ores in which the precious metals are important secondary economic constituents, (6) ores in which the precious metals are by-products of treatment.

Gold placers. Methods of treatment differ principally because of mining problems, the requirements of tailing disposal, and the water supply rather than because of the concentrating problem.

Panning and rocking. Very small high-grade placers where water is scarce are worked by panning or rocking (Sec. 8, Arts. 8 and 9).

Shoveling-in. When the deposits are larger, low-lying and not cemented, and more water is available, the long tom or a simple sluice line is used (Sec. 8, Art. 11). With more water, a HYDRAULIC ELEVATOR may be used for this type of deposit, or various mechanical means may be used to elevate the feed to the sluice line.

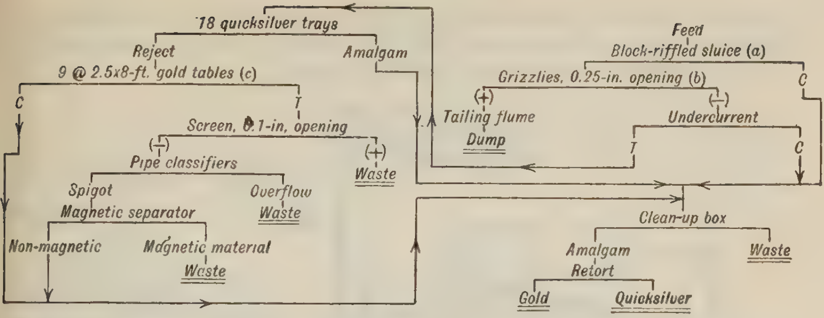
Hydraulic mining. When the deposits are large, lie well above the point of tailing disposal, and there is an abundance of water available under sufficient pressure, the gravel is broken down by hydraulic giants, transported to the concentrating plant by the water used for excavation, and flowed through sluices, usually fitted with undercurrents (Sec. 8, Art. 11) to catch the fine gold that cannot be held in the main sluice line on account of the strong current necessary to move the coarse gravel.

Camp Carson Mining and Power Co. Fig. 71. (*100 J 472.*)

Location: Union County, Ore.
Ore: Fine gold in loose gravel. Material as low as 8 to 9 cents per cu. yd. can be treated.
Cost, including hydraulicking, 5¢ per cu. yd.

Dredges are used when the deposit is low-lying, of large lateral extent, and not too great depth. The flow-sheet of the gold-saving devices depends on the character of the gravel and the requirements of tailing disposal.

Sluice dredge (Fig. 72) is best adapted for saving coarse gold and can be used when the percentage of large boulders is not too great. In a typical



a, The coarser gold is recovered in two lengths. (See Sec. 8, Art. 11.) *b*, In bottom of sluice. Made of round bars, about ¾-in. diameter, mounted in comb fashion and set in sluice with free ends downstream and overlapping the following grizzly. 8 sets used = about 16 ft. along bottom. *c*, Slope, 2 in. per ft.

Fig. 71.—Camp Carson Mining and Power Co.

sluice dredge the gravel passes first over a wash trommel with 3- to 4-in. openings, oversize discharges over the side of the boat into the pond, and undersize goes through a string of sluices, usually with an undercurrent and gold tables for the fine material. Fine tailing is discharged on top of the coarse from previous working.

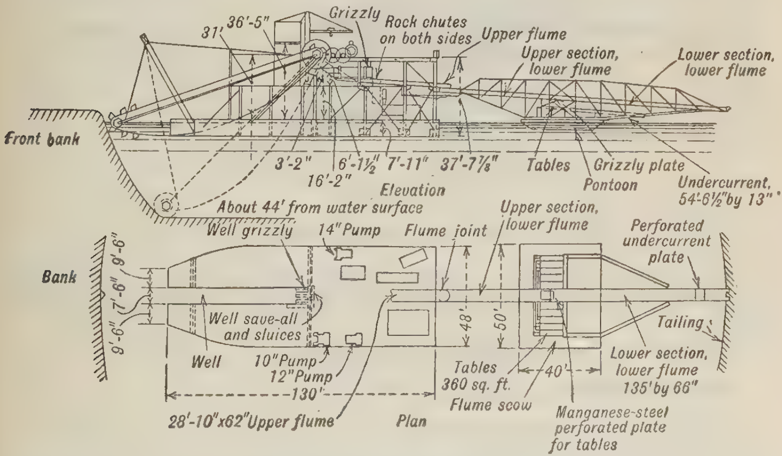


Fig. 72.—Sluice dredge.

Stacker dredge (Fig. 73) receives the bucket-line discharge in a large wash trommel with ½- to ¾-in. apertures; the oversize is discharged onto a stacking conveyor while the undersize goes first to a series of tables in parallel, thence through short sluices, frequently a number in parallel, to the pond. The stacker dredge is a better saver of fine gold than the sluice dredge, on account of the smaller depth and smaller velocity of the streams passing over the riffles, but it loses very coarse gold that will not pass the wash-trommel

perforations and also fine gold that balls up with clay and goes to the stacker. It also has the disadvantage that the coarse tailing is stacked on top of the fine, which ruins the land for any agricultural use.

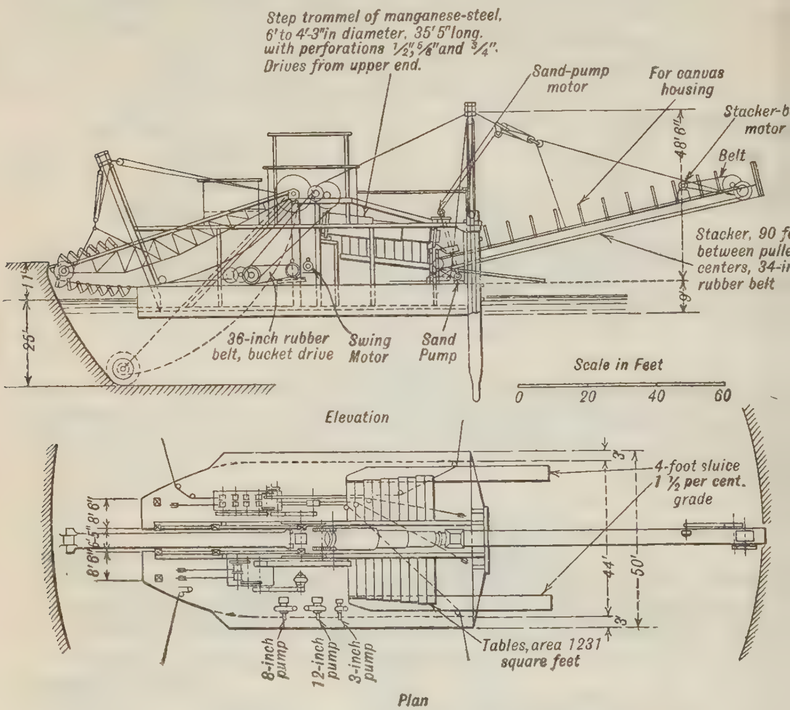

Fig. 73.—Stacker dredge.

Details of the gold-saving devices on four Montana sluices are given in Table 52. For further detail see *Bul. 121* and *127 USBM* and *Bul. 263 USGS.*

Clayey gravel requires thorough disintegration.

Siberian gravel mine. Fig. 74. (*105 J 859.*)

Ore: Clayey gravel containing free gold.

Capacity: 250 cu. yd. per 24 hr.

Water: 250 miner's inches (= @ 6 sec. ft.). This is a washing duty of 1 cu. yd. per 24 hr. per miner's inch. Hutchins calls attention to the fact that the corresponding figure for gold dredging is frequently 10 cu. yd.; for hydraulicking, 5 cu. yd.; for cemented gravel in California drift mines, 6 to 12 cu. yd.; and that even in hydraulic elevating the duty is greater than 1. cu. yd.

Recovery: About 67 per cent. Much of the loss was in clay balls from the first disintegrator.

Simple free-milling ores comprise the great bulk of the gold ores now mined. Substantially all of them are treated by amalgamation and/or cyanidation. (See Sec. 15.)

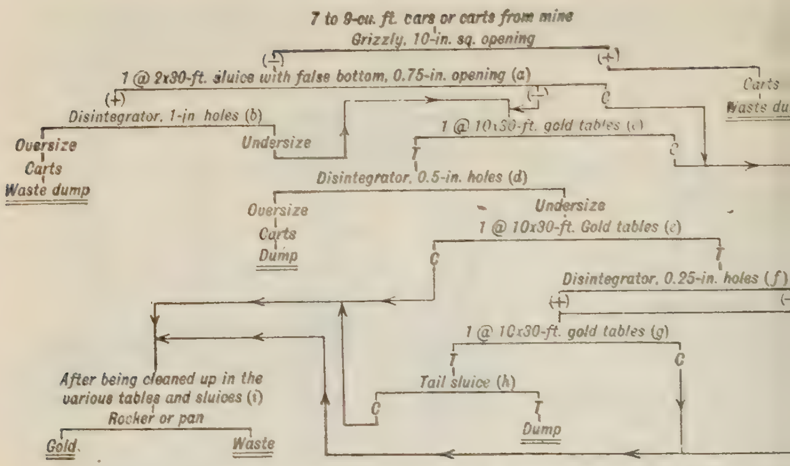
a Stepped, cylindrical. *b* Round hole. *c* A gold-saving table to treat the spill around the head of the digging ladder. *d* Actual recovery not ascertainable on account of practical impossibility of sampling feed.

Simple sulphide gold-silver ores

These ores contain gold and small amounts of silver intimately associated with sulphides in a simple rocky gangue. The usual method of treatment is concentration of the gold-bearing sulphides into small bulk, followed by smelting or hydro-metallurgical treatment of the concentrate. If the tailing



a, Slope, 18 in. in 12 ft. *b*, Locally called *chasha*. Shallow pan, 10 to 12 ft. diamete cast-iron bottom with perforations. 4 to 8 radial arms on a central spindle. Fig. 74.—Siberian gravel mine.

is of sufficiently high grade, it is cyanided separately. Alaska Gastineau typical of the first and the Mother Lode mills, California, making a gravit concentrate on tables and vanners, with grinding, amalgamation and cyanid treatment of concentrate and cyanidation of tailing are typical of the secon method of treatment.

Alaska-Gastineau Mining Co. Fig. 75. (Q. 63 A 488.)

Location: Thane, Alaska.

Ore: Gold and silver associated with pyrrhotite, galena, arsenical pyrite and sphale in quartz lenses occurring in slate, schist and meta-gabbro, which latter also carry mine values. Analysis, per cent: SiO_2, 59.7; Fe, 5.2; Al_2O_3, 21.4; CaO, 5.0; MgO, 0.4; S, 1 Pb, 0.1; Zn, 0.2.

Capacity: 10,000 tons per 24 hr.

Assays, Au: Feed, $1.25; concentrate, containing about 44 per cent. of the tot gold recovered, $400; dead bullion contains balance of gold recovered; tailing, $0.2 (1920, $0.17.)

Recovery: 75 to 80 per cent.

Ratio of concentration: 1000 or 1200 : 1.

Power: 13.3 hp.-hr. per ton milled distributed as follows: Coarse crushing, 0.52; f crushing, 6.02; concentrating, 4.78; re-treatment plant, 0.47; pumping, 1.17; lighting, 0.3 motor generator, 0.93.

Water: 5.2 tons per ton milled.

Labor: 78.9 tons per man-shift, operating.

Distances: Mine to mill, 3½ miles; mill to smelter, 2000 miles; water, a part comes mile by flume, the balance is pumped 1000 ft. with a consumption of 700 hp.; powe transmitted 8 miles at 22,000 volts.

Costs in 1917, before the period of full tonnage, but also before the war increase labor and supply prices were, in dollars per ton: Coarse crushing, 0.02804; fine crushi 0.09432; concentrating, 0.05136; general mill, 0.02778; power and light, 0.01467; gene

overhead, 0.02340; total, 0.23957. Of this total cost labor was 40.6 per cent.; supplies, including power, 22.8 per cent.; repairs, 15.8 per cent.; sundries, 20.8 per cent. In 1920 the total milling cost was $0.28 per ton.

General: Steeply sloping millsite. Sizing-assay tests of feed to primary Garfield tables (concentrating-mill feed), re-treatment-plant tailing and general tailing are given in Table 53.

Table 53. Sizing-assay tests, Alaska Gastineau mill

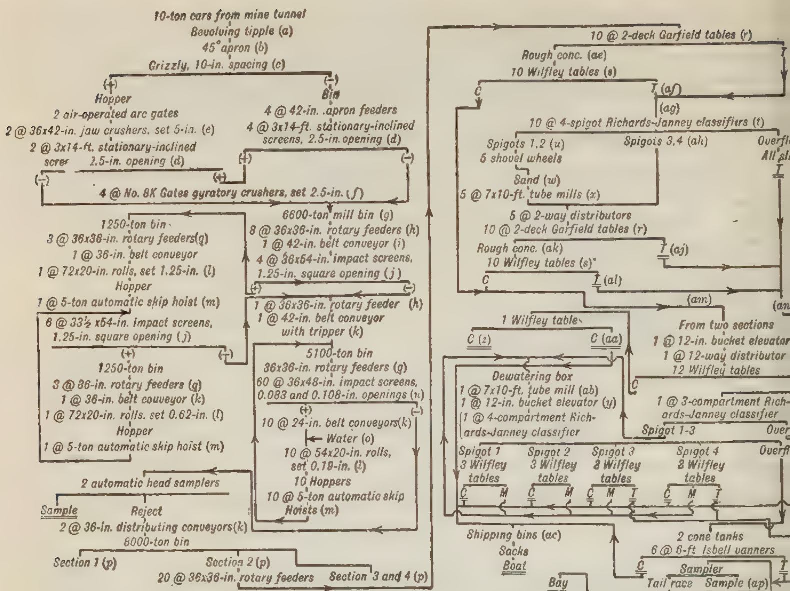
Summary. Table concentration by roughing-cleaning system. CRUSHING: Jaw crusher from 30-in. to 5-in.; gyratory from 10-in. to 2.5-in.; 2-stage roll crushing from 2.5- to 1-in.; one-stage choke crushing in rolls from 1-in. to 0.10-in.; tube mills from 0.1- to 0.04-in. CONCENTRATION: Roughing on primary Garfield tables with re-treatment of rough concentrate on Wilfley tables and re-grinding of coarse tailing followed by a similar roughing-cleaning step with rejection of tailing from both roughing and cleaning tables. Concentrate from the above operations was re-treated in two stages. The first stage was a roughing-cleaning operation on Wilfley tables making finished concentrate and tailing, the coarse part of which was re-ground, classified, and the spigot products re-treated in one pass over Wilfley tables that made finished concentrate and tailing and a middling returned to the re-grinding mill. It is an interesting feature of this flow-sheet that the slime is low-grade and that, consequently, the hydraulic classifiers are used as concentrators in so far as they reject overflow to the tail race.

This mill ceased operations early in 1921 after a life of some six years, during the last three of which operations were conducted at a loss. The causes of failure were incorrect sampling of the ore body as a result of which it was estimated that the grade of the feed would be between $1.50 and $1.75 while actual mining produced ore running nearer $1.25 per ton; failure to foresee that considerable waste would have to be mined with the ore, resulting in further reduction in grade of mill feed; and increases in labor and supply prices. The latter difficulty was nearly altogether overcome, in so far as the mill was concerned, as is evidenced by the fact that in 1920 the cost of milling was only $0.04 per ton higher than in 1917, but the 1920 mill heads carried only $0.85 gold, and while the yield was $0.68 per ton (80 per cent. recovery) this was insufficient to cover mining and milling costs.

Notwithstanding the failure of the enterprise, this mill was eminently well fitted to the treatment of a low-grade ore containing relatively coarse gold intimately associated with sulphides. The use of automatic skips for elevating in the roll circuits was unique in concentrating-mill practice, although they have been used in other lines.



a, Takes 4 cars at a time. Actuated through friction clutch and fitted with ba brake. 50-hp. motor installed is sufficient for two tipples. *b,* Covered with discarded r shells, 1 in. thick, straightened at red heat under steam hammer. *c,* 52 ft. FIG. 75.—Alaska-Gastineau Mining Co.

Complex and refractory gold and silver ores

This class includes both ores in which the precious metals constitute t principal economic value and others in which the precious metals are secondary importance. The common characteristic is insusceptibility treatment by amalgamation and cyanidation. This may be due to the fa that the precious metals will not amalgamate and occur in association wi substances that consume undue amounts of cyanide, or that they occur particles of such size that solution requires an unduly long time, or in su small quantity that without the recovery of the associated metals treatme

Tons per stamp per 24 hr. = 6.4. Sizing test of product, per cent.: +6-mesh, 36.0; +8, 9.9; +10, 8.2; +14, 8.5; +20, 4.4; +28, 6.6; +35, 3.9; +48, 3.9; +65, 3.1; +100, 2.5; +150, 2.2; +200, 1.1; −200, 9.6.

Location: Cobalt, Ont.

Ore: Native silver with niccolite, smaltite, chalcopyrite and some argentite, galena and pyrite in quartz and calcite veinlets in diabase.

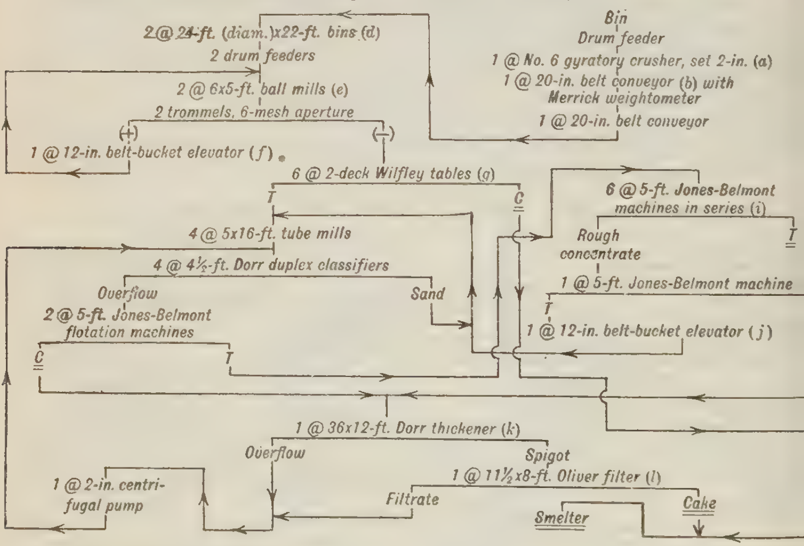
Capacity: 360 tons per 24 hr.

Assays: See notes *a*, *e*, *f*, *h*, *i*, Fig. 76.

Cost: $1.80 per ton milled.

Summary. Gravity concentration and flotation. CRUSHING: Jaw crusher to 3-in., gyratory to 1½-in., stamps to ½-in., 2-stage open-circuit tube milling to −60-mesh. CONCENTRATION: Roughing and cleaning of sands on shaking tables at −½-in. to 100-mesh; pneumatic flotation in three circuits, *viz.:* primary slimes, table and flotation middling, and primary-flotation tailing; concentrate in each circuit cleaned twice.

Belmont Surf Inlet Mine. Fig. 77. (*Q, 105 J 720.*)



a, 50-hp. motor. Run 8 hr. per day. *b*, 419 ft. long. Slope, −3.2 in. per ft. 280 ft. per min. *d*, Built of logs. Installed in duplicate. *g*, 260 @ 0.75-in. strokes per min. *i*, See Sec. 12, Art. 15. *j*, 12 × 6 × 6-in. buckets, spaced 18 in.; 23-ft. lift. 36- and 30-in. head and tail pulleys, respectively. *k*, 1 rev. in 8 min. 86 per cent. moisture in feed, 30 to 40 per cent. in spigot. *l*, See Sec. 17, Art. 3.

FIG. 77.—Belmont-Surf Inlet mill.

Location: Surf Inlet, B. C.

Ore: Gold with a small amount of silver and copper and iron sulphide in hard white quartz.

Capacity: 350 to 400 tons per 24 hr.

Assays, Au, oz. per ton: Mill feed, 0.6; table concentrate, 5.36; table tailing, 0.33; flotation concentrate, 8.2 oz. Combined insoluble, 14 per cent.

Recovery: Gravity, 47.8 per cent.; total, 92.2 per cent.

Ratio of concentration ranges from 8 : 1 to 18 : 1, depending on pyritic content of feed.

Running time: 95 per cent. of possible.

Power: 42 hp.-hr. per ton milled.

Labor: 40 tons per man-shift, operating; 60 tons per man-shift on repairs.

Water: 3 to 4 tons per ton milled.

Distances: Mine at mill; mill to smelter, 500 miles; power transmitted, 5 miles at 23,000 volts; water pumped ⅓ mile from lake with consumption of 30 hp.

General: 130 miles from railroad. Steeply sloping millsite.

Summary. Tabling and flotation. CRUSHING: Gyratory from 12- to 2-in.; ball mills from 2.5- to 0.12-in.; tube mills from 0.12-in. to 56-mesh (70 per cent. −200-mesh). CONCENTRATION: Tabling at −0.12-in. to remove coarse gold; flotation by combination routing for balance of treatment.

Le Roi No. 2. Fig. 78. *(114 J 1118.)*

Location: Rossland, B. C.

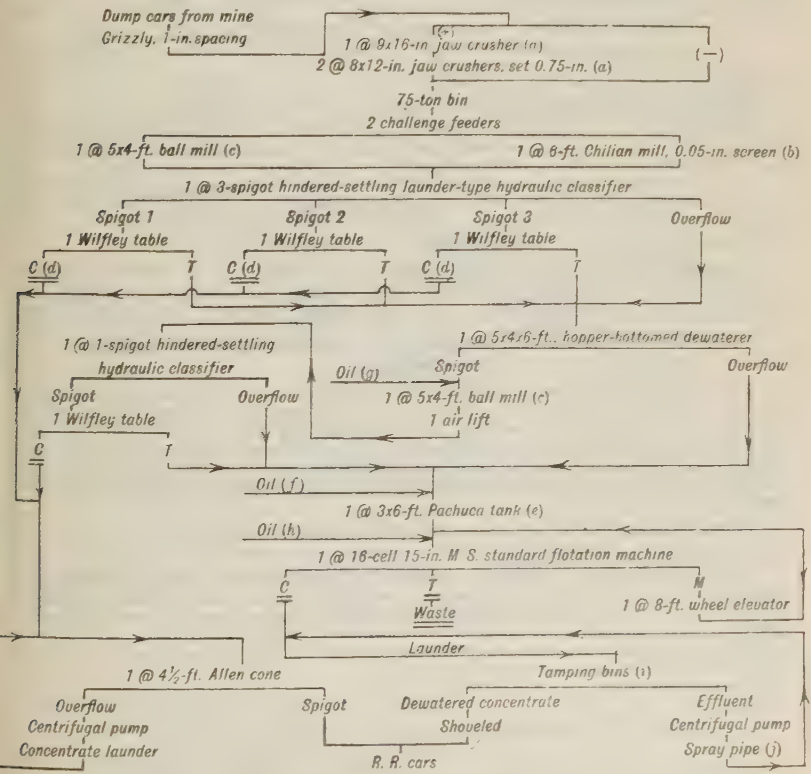


FIG. 78.—Le Roi No. 2 mill.

a, Repairs on the 3 crushers amount to $0.025 per ton crushed, indicating extreme hardness of ore. *b,* See Sec. 4, Table 88. *c,* See Sec. 4, Table 4. *d,* Principally pyrrhotite: assay, 1.0 oz. Au, 1.5 per cent. Cu. *e,* 2 air-lifts, one for circulation and one for discharge. *f,* Pine oil, @ 0.25 lb. per ton. *g,* Water-gas tar, @ 1 lb. per ton. *h,* Less than 0.25 lb.

per ton of the above oils added to middling cells as needed. *i,* Tank 1 ft. deep, 2 ft. wide, 22 ft. long, fed at one end, burlap screen at opposite end, effluent to a similar tank. Transverse baffles 6 in. high in bottom of tanks. Settled concentrate tamped for 2 or 3 min. every 2 or 3 hr. Compacted concentrate shoveled out as it accumulates. Product, 10 to 15 per cent. water. *j,* Over concentrate launder.

Ore: Gold-bearing chalcopyrite and barren pyrrhotite in augite porphyrite. Chalcopyrite finely disseminated in coarse pyrrhotite and in country rock. Gold is about 80 per cent. of total value. It occurs free in both sulphide and gangue rock.

Capacity: 100 to 150 tons per 24 hr., dependent upon water supply.

Assays: Concentrating ore, 0.15 to 0.50 oz. Au; 0 to 0.6 oz. Ag; 0.5 to 1.0 per cent Cu. Table 54 gives representative performance over a considerable period.

Table 54. Milling results at Le Roi No. 2. (*After Lay*)

	Au, oz. per ton	Cu, per cent.	Fe as sulphide, per cent.
Mill feed	0.155	0.42	8.1
Flotation feed	0.074	0.30	6.3
Table concentrate	0.93	1.40	29.6
Flotation concentrate	0.91	4.66	28.5
Flotation tailing	0.043	0.10	5.2

Recovery: Au, 75 per cent.; Cu, 80 per cent.

Ratio of concentration: 10 : 1.

Water: Scarcity prohibits erection of a large concentrator at the mine.

General: Gold recovery is more important than copper on account of the fact that the smelter pays for 95 per cent. of the gold in concentrate while only 65 per cent. of the copper is paid for, after deductions for treatment, etc.

Costs, dollars per ton of mill feed: coarse crushing, steel, 0.025; primary grinding, steel, 0.345; secondary grinding, steel, 0.165; power for crushing and tabling, 0.120; labor for crushing and tabling, 0.375; sundries, crushing and tabling, 0.065; flotation: oil, 0.072; labor, 0.148; power, 0.040; royalty and sundry, 0.050; total, 1.405.

Summary. Tabling followed by differential flotation. CRUSHING: 2-stage jaw crushing from 8- to 1-in.; 2-stage ball milling from −1-in. to 48-mesh. CONCENTRATION: Tabling after hydraulic classification in two stages with intermediate re-grinding of primary-table tailing; differential flotation of primary slime and secondary-table tailing.

Lay points out that higher recovery of both gold and copper could be made by collective flotation, but that the resulting higher recovery of iron would lower the financial return because of a combined freight and smelting charge of $6.40 per ton of concentrate. He also cites an experiment with heap-oxidized ore, *i.e.*, ore exposed to the weather for several months, that yielded a flotation concentrate containing 8 per cent. Cu, with copper and gold recoveries equal o or better than the present, and suggests the possibility of such treatment.

Seoul Mining Co. Fig. 79. (*33 IMM 3; 119 P 805.*)

Location: Tul Mi Chung, Korea.

Ore: Highly complex. Gold and some silver with chalcopyrite, pyrite, mispickel and small amounts of lollingite (Fe_2As_3), galena, blende, bismuth and molybdenum minerals in a contact-metamorphic gangue containing much garnet, calcite, diopside, serpentine, mica, epidote, zoisite, actinolite, etc.

Analysis, per cent: Cu, 1.18; Fe, 7.45; As, 0.37; S, 1.76; Pb, 0.05; Zn, 0.30; Bi, 0.11; SiO_2, 67.07; Al_2O_3, 0.69; CaO, 10.76; MgO, 1.43.

Capacity: 450 tons per 24 hr.

Assays:

	Au, oz. per ton	Ag, oz. per ton	Cu, per cent.

a Electricians' labor included with power. *b* Mill labor, 20 to 35 cents per 8-hr. shift.

Summary. Flotation, combination routing. CRUSHING: Jaw crusher from 18- to 3-in.; jaw crusher from 4- to-1 in.; ball, pebble and ball mill in series from 1-in. to 10 per cent. +100-mesh. CONCENTRATION: 3-stage roughing with one cleaning of the concentrate from the first and second roughers and cleaning and re-cleaning of concentrate from the scavenger rougher.

The difficult problems at this plant are to save the gold and to keep down the tonnage of concentrate. The gold is finely divided and, while some occurs free, much is very closely associated with the chalcopyrite and the lollingite. The latter mineral does not float readily, and in order to bring it up, it is necessary to float considerable pyrite. Even thus, considerable gold is lost. Concentrate handling, freight and smelting cost $30 to $40 per ton of concentrate or upward or $1 per ton milled, hence it is not economically possible to increase gold recovery at the expense of any decided increase in tonnage of concentrate produced.

Mount Morgan mine. Fig. 80. (*34 IMM, 448.*)

Location: Mount Morgan, Queensland, Australia.

Ore: Gold with a trace of silver, pyrite and chalcopyrite in quartz. Gold is very finely disseminated in the quartz.

Capacity: 800 tons per 24 hr.

Assays:

	Au, oz., per ton	Cu, per cent.	Fe, per cent.	SiO_2, per cent.
Feed	0.293	2.00	15.00	64.74
Jig concentrate	0.318	1.84	38.67	15.65
Table concentrate	0.562	3.47	39.98	12.43
Flotation concentrate	1.113	11.99	26.06	29.75
Tailing	0.0104	0.19	3.54	....

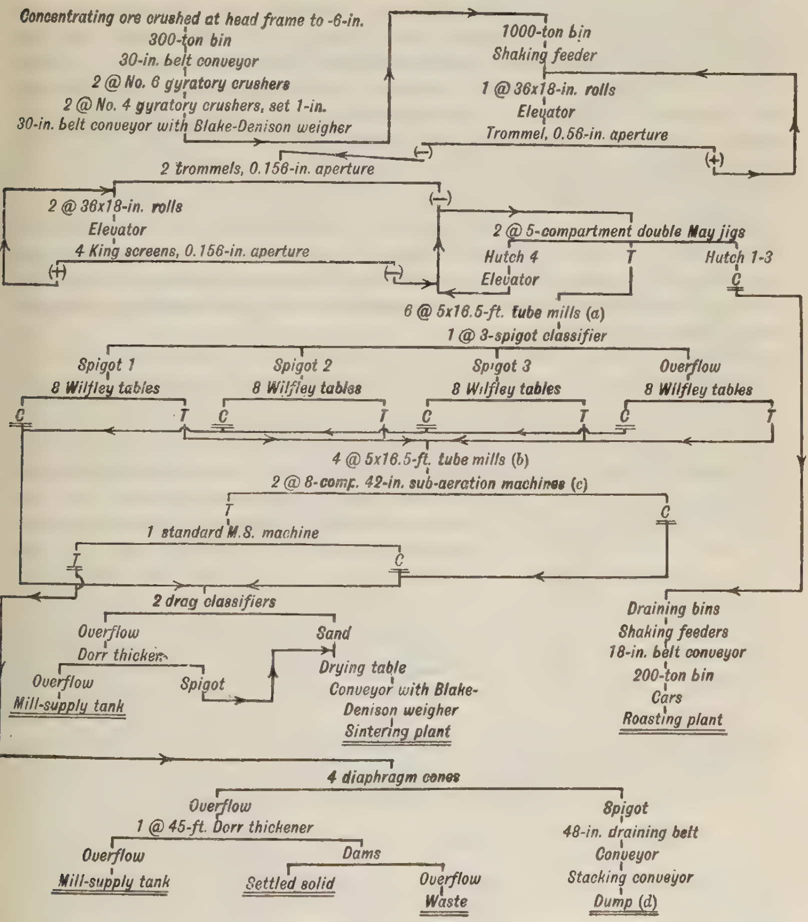
Recovery: 77.08 per cent. Au; 93.74 per cent. Cu.

Ratio of concentration: 2.81 : 1.

Water: new, 1 ton per ton milled.

Summary. Jigging, tabling, flotation. CRUSHING: Coarse breaking to 6-in.; 2-stage crushing in gyratories from 6- to 1-in.; 2-stage roll crushing from

1- to 0.156-in.; 2-stage tube milling from 0.156- to 0.0083-in. with intermediate tabling. Concentration: Jigging at −0.156-in.; tabling at 20-mesh; floating at 60-mesh, making pyritic concentrate in the gravity steps and a tailing for re-treatment; a copper concentrate and final tailing by flotation.



a, Grinding to 13 per cent. +40-mesh (0.0125-in.). *b*, Grinding to 4 per cent. +60-mesh (0.0083-in.). *c*, 18-in. shrouded impellers. *d*, Drawn as desired through tunnel and sent by aerial tram to mine for filling.

Fig. 80.—Mount Morgan mill.

20. Graphite (C)

Properties. Soft, amorphous or flaky, resists heat and chemical action, conducts electricity, and has good lubricating qualities.

Uses. Principal use is in the manufacture of crucibles. This industry accounts for 85 to 90 per cent. of domestic consumption of crystalline graphite. About 80 per cent. of the graphite in crucible mixes is Ceylon graphite, and, due to the belief of crucible manufacturers in the superiority of this variety, not more than 20 per cent. of the crucible demand

may be considered as a market for domestic production. Other uses for the flaky variety are as a lubricant, a filler for asbestos and metal packings, oil-less bearing compounds, pipe-joint compounds, paint, and shot polishing. AMORPHOUS variety is used for foundry stove polish and lead pencils.

Ores. Graphite is a mineral form of the element carbon (C); SP. GR. 2.1 to 2.9, the lower figure corresponding to greater purity. The usual impurity is silicious material occurring between adjacent laminæ of graphite. LUSTER is usually metallic. Occurs in laminated or sooty masses in vein deposits and as disseminated flakes or grains in metamorphic rocks. Flakes usually range in size from 0.5-in. down. Mica and chlorite are the most troublesome gangue minerals. The best-known deposits are the veins of flake graphite in Ceylon and of the amorphous variety in Mexico and Korea; the disseminated deposits of flake in Central Europe, eastern Canada and eastern United States.

Production. Average yearly post-war world production has been about 100,000 tons, of which the United States has contributed between 3000 and 10,000 tons. Austria, Czecho-Slovakia and Germany combined accounted for from 50 to 60 per cent. of the world production and Ceylon and Madagascar from 15 to 25 per cent.

Selling. Ceylon graphite is hand sorted into four grades, *viz.:* LUMP, from about 1- in. to 1/16-in.; CHIP, about 1/16-in.; DUST, the granular material finer than chip; and FLYING DUST, substantially impalpable powder. Flake graphite is sold in three grades, *viz.:* No. 1 FLAKE, passing 16-mesh and remaining on 90- or 100-mesh screen and having a graphitic carbon content of about 90 per cent.; No. 2 FLAKE, with slightly lower carbon content and lying between 60- and 120- to 140-mesh; and DUST with as low as 30 to 40 per cent. graphitic-carbon content and passing the fine screens. A sizing test of No. 1 Alabama flake is given in Table 55. Good-grade AMORPHOUS GRAPHITE should contain at least 80 per cent. graphitic carbon and should be brilliantly black and unctuous. Analyses of first-grade crystalline graphite from various producing sections is given in Table 56. Pre-war PRICE of best Ceylon graphite was 8 to 10¢ per lb. There was a slump in 1924 to 6¢. Sept.

Table 55. Sizing test of No. 1 Alabama flake graphite. (*After Dub*)

Screen, mesh	Weight, per cent.
+35	6.5
65	45.6
100	38.2
−100	9.7

Table 56. Analyses of first-grade crystalline graphite. (*After Brumell. 22 CMI 403 and Dub, Preparation of crucible graphite, USBM, 1918*)

1925, prices for Ceylon were 8½ @ 9¢ for lump, 6½ @ 7¢ for chip, 3½ @ 5¢ for dust; flake was quoted at 10 @ 30¢ per lb.

Treatment. Graphite from disseminated deposits must be concentrated before marketing and concentrate is usually further refined (*i.e.*, concentrated) by the larger purchasers before use. Large flake and high-grade concentrate are more important considerations in milling than high recovery. Substantially all kinds of concentrating processes have been tried in graphite-ore treatment and practically all failed prior to the introduction of froth flotation, Brumell (*22 CMI 378*), in a comprehensive summary of the American graphite industry, classifies the concentrating equipment in 38 Alabama mills in 1919 as follows: skin-flotation plants, 14½; froth-flotation, 15½; wet-gravity concentration, 5; electrostatic, 2; dry concentration, 1. He says that the mills using SKIN FLOTATION rarely made recoveries greater than 50 per cent. and usually about 35 per cent. The ELECTROSTATIC MILL was said to be highly profitable, but no operating data are available. The flow-sheet consisted of crushers and rolls in series to free the flake, grading and rough concentration by screens and air classifiers, and finishing on a Huff electrostatic machine. LOG-WASHER MILLS, classed above as wet-gravity concentration, treat the crushed material in log washers to which a small amount of kerosene is added. Overflow is concentrate. It is screened, undersize rejected, oversize washed on a cement floor, the residue being wasted, while the light washings are drained, dried and sent to the finishing mill. GRAVITY-CONCENTRATING MILLS using classifiers, shaking tables and film-sizing devices (buddles and the like) have been tried and failed many times. PNEUMATIC MILLS were probably the most successful from a concentrating standpoint, prior to froth flotation, but operating and mechanical difficulties were great on account of excessive dust. The flow-sheet of the American Graphite Co. is typical of a modern FROTH-FLOTATION MILL.

Graphite finishing mills treat the dried concentrate from the concentrating mills. The essential features of finishing practice are grinding in smooth-surfaced polishing rolls, buhr stones or pebble mills, de-dusting in crude air classifiers, usually of horizontal-current type, and sizing the de-dusted product into merchantable grades. Brumell (*loc. cit.*) cites two cases of such finishing treatment; in one a product containing 71.8 per cent. graphitic carbon was raised to 85.7 per cent.; in the other, 51-per cent. material was raised to 82-per cent.

The action of the grinders in finishing is to pulverize the more or less brittle gangue material while the soft, tough flake is flattened out but not broken. Hence subsequent separation into coarse and fine results in concentration of graphite in the coarser grades.

American Graphite Co. Fig. 81. (*120 P 567.*)

Location: Ticonderoga, N. Y.
Ore: Flake graphite in quartzitic schist.
Capacity: 100 tons per 24 hr.
Assays, per cent. graphitic carbon: Feed, 5.5 aver.; total conc., 86.5; coarse flake, 91.
Recovery (1919): 87 per cent.

Summary. Pneumatic flotation; repeated cleaning of concentrate with intermediate re-grinding in two stages.

Notes to Fig. 81.

a, Hand fed. *b,* Large circulating load is carried in order to grind flake as little as possible. *c,* 28-mesh. Much flake graphite overflows on account of presence of oil. *d,* Introduction of Deister cone classifiers at this point increased overflow of flake graphite from classifier system. The hydraulic-classifier sands went to the Dorr classifier, the overflow joined the Dorr overflow. *e,* Rectangular, one side canvas. Material drains in 8 hr. to about 40 per cent. moisture. Shoveled out by hand. *f,* Sides of all cleaners raised about 12 in.; 3 cross baffles, the lowest, at the discharge end, about the height of the original overflow, the next raised 3 in. and the feed-end baffle 6 in. Froth cascades over these and overflows at the discharge end; this aids in raising the grade of concentrate.

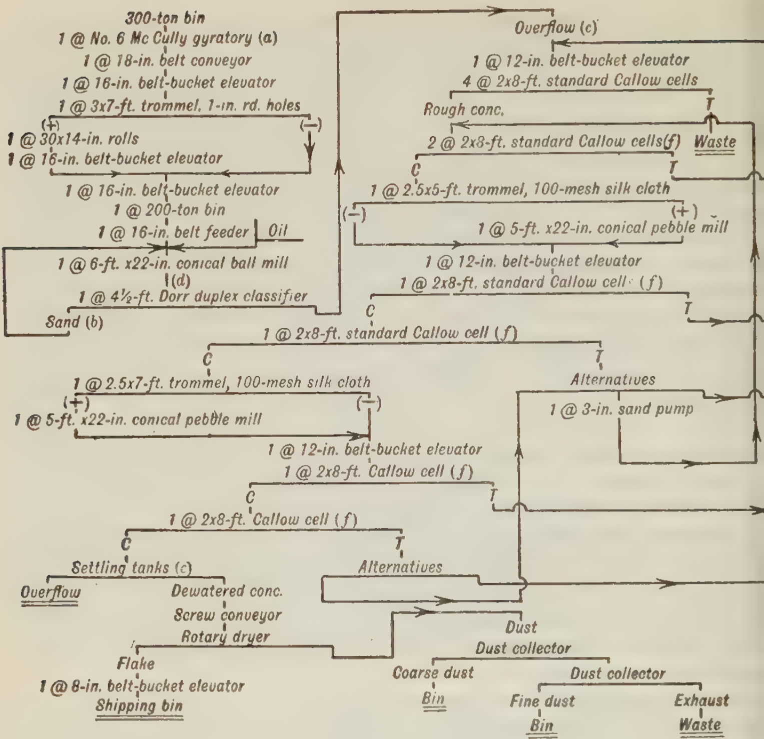

FIG. 81.—American Graphite Co.

21. Iron, Fe

Properties. Metal; gray-white, lustrous, tenacious, comparatively soft and ducti when pure, magnetic (see also Table 1). AT. WGT., 55.8. In compact form not attacke by dry air, but when very finely divided, as when produced by reduction with hydrogen, burns in dry air when gently warmed. It is attacked by moist air, with the formation RUST, a complex mixture of oxide and hydroxide of iron. Water is decomposed by iron all temperatures. Iron is dissolved by even the weakest acids, forming the correspondir bi-valent salts with iron as the base. These pass easily by oxidation into salts in whi the iron ion is tri-valent. Iron also enters into combination as a part of the acid constit ent of certain salts. Alloys of iron are numerous and extremely important commerciall

Uses of iron are multitudinous; it is used almost entirely as cast iron or steel, both which are alloys or mixtures of iron with carbon and other elements such as phosphoru manganese, chromium, nickel, tungsten, vanadium, molybdenum, cobalt, silicon, titaniu

Ores. The economic minerals are hematite, magnetite, limonite, siderit and very occasionally pyrite. For a deposit of one of the above minerals constitute an ore it must be favorably located with respect to fluxes, fuel ar markets; it must be of high grade; must occur in large quantity; and must l so that mining will be possible on a large scale at comparatively low cos Furthermore, it should be relatively free of titanium, phosphorus and sulphu which are harmful in the finished iron and steel products and difficult impossible to eliminate. Analyses of typical domestic ores are shown Table 57.

Table 60. Average prices of iron ore per long ton at the mines

Year	Lake Superior district	South-eastern district	North-eastern district
1920	$4.25	$2.88	$4.90
1921	3.58	1.83	3.75
1922	3.33	1.74	2.33
1923	3.62	2.31	3.35
1924	3.06	2.13	2.59

Treatment. Most of the iron ore now mined and mined in the past ha been sufficiently high grade to smelt without concentration, but the end of th known high-grade deposits in the United States is in sight and an increasin tonnage of lower-grade ores is concentrated every year.

The simplest form of beneficiation is typified by that at the SUSQUEHANNA mine a Hibbing, Minn. (*102 J 787*) where masses of taconite are scattered through the hematite In earlier operations the taconite was picked out ahead of the steam shovels and haule away in dump cars. This expensive operation was replaced by screening. The ore i loaded by steam shovel into 12-cu. yd. air-operated side-dump cars, taken to the screenin plant and dumped onto a flat grizzly with 30-in. spacing. Oversize is sledged through into bin. From the bin the ore is drawn into a 5 × 24-ft. revolving stone screen with 2-in round holes. Oversize is waste, which discharges into a car-loading bin whence it is haule to a rock dump. Undersize goes to the shipping bins. Capacity of this plant is abou 250 tons per hr. and it requires only about 30 hp.

When, as is the case in many of the Lake Superior mills and the souther mines, the impurity in the ore is fine sand and clay the usual plant consist of screens and a log washer, supplemented in some cases by shaking tables fo treating the log-washer overflow. See Fig. 82.

In 1912 a complicated experimental plant was built for the AMERICAN-BOSTON MININ Co. (*95 J 1016*). It involved stage crushing through 10-mm. in gyratory crushers and roll 2-stage jigging of closely sized feeds (−10 +7-mm., −7 +4-mm., −4 +2-mm., an −2-mm.) and treatment of −20-mesh material by classification and tabling. This practic has not been followed by other companies, however, and is undoubtedly too expensive t allow the products to compete in the present markets.

MAGNETIC-IRON ORES carrying 25 to 45 per cent. Fe occur in enormou deposits underlying large areas in northern New Jersey and eastern New York High-grade deposits in these regions have been mined for over 100 years The coarsely crystalline, lower-grade deposits are concentrated by dry magneti methods typified by the flow-sheets of Witherbee, Sherman Co., mills Nos. and 5 (Figs. 85 and 86).

The finely disseminated deposits have not yet been worked profitably. At one of these, the BENSON mine, a plant was built in which the ore was crushed in stages from run-of-mine size to 18-mesh by 72 × 60-in. Edison giant rolls, 40 × 42-in. jaw crusher, 2 sets of 36 × 36-in. Edison rolls in series and 8 × 6-ft. ball mills, then concentrated in 2 stages on Gröndal wet-drum separators and the concentrate nodulized. At REPLOGLE STEEL Co. the economic minerals are magnetite and the non-metallic martite (Fe_2O_3); concentration is effected by dry magnetic separation followed by tabling (Fig. 87). At PENNSYLVANIA STEEL Co., Lebanon, Pa., magnetite occurs with pyrite and chalcopyrite (Fig. 90). The most recent plant is that of the MESABI IRON Co. (Fig. 88), treating a very finely disseminated low-grade magnetite ore. This plant is probably prophetic, in its essentials, of future practice in magnetic iron-ore concentration.

Alabama iron-ore washer. Fig. 82. *(108 P 458.)*

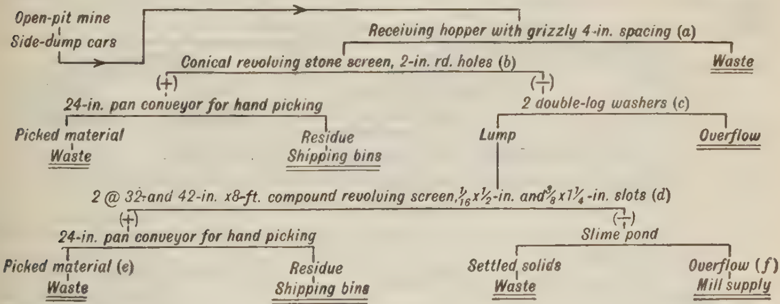
Ore: Limonite in clay and gravel.

Capacity: 100 to 150 cu. yd. per hr.

Ratio of concentration varies in this field from 3 : 1 to 12 : 1, average about 5 : 1, making a concentrate carrying 42 to 50 per cent. Fe, less than 1 per cent. Mn and 0.5 to 1 per cent. P.

Water: About 2000 gal. per ton of ore.

Cost, with a ratio of concentration not greater than 6 : 1, was about \$0.50 to \$0.75 per ton in 1914.



a, Hopper V-shaped, 5 to 6 ft. wide at top, 50 to 60 ft. long, 2 to 3 ft. deep at the upper end; bottom a flume 1½ ft. wide and sloping 2½ in. per ft. Grizzly of heavy rails set on 1½- to 2-in. per ft. slope and spaced 4 in. forms a false bottom. Oversize is sledged and picked on grizzly. Undersize is flushed down flume with water. *b,* With strong washing spray. *c,* Logs 18-in. octagonal and 20 to 30 ft. long, set 38 in. center to center. Blades 9 to 10 in. long, 5¼ in. wide and 1¼ in. thick. Logs slope 1 in. per ft. Trough flat-bottomed, 7 ft. 4 in. wide, about 4 ft. deep at lower end and 2 ft. deep at upper. Speed, 12 to 15 r.p.m. *d,* Fitted with strong internal wash sprays. *e,* Clay balls and gravel. *f,* About 50 per cent.

FIG. 82.—Typical Alabama iron-ore washer.

Oliver Iron Mining Co. Fig. 83. *(Q; 35 MEW 949; 107 J 683.)*

Location: Coleraine, Minn.

Ore: Loose mixture of hematite and taconite sand.

Capacity: 400 tons per unit per hr. (48,000 tons per 24 hr. for 5 units).

Assays, aver.:

	Fe, per cent.	SiO_2, per cent.	Mn, per cent.	P, per cent.	H_2O, per cent.
Feed	43.5	32.1	0.24	0.054	9.75

Ratio of concentration: 1.6 : 1.
Labor: Tons concentrate per man per day, based on total labor: 75 to 90.
Power: 2.8 hp.-hr. per ton (installed), exclusive of water supply.
Water consumption: 300 to 350 gal. per ton of crude ore.
Distance mine to mill: 2 to 5 miles.
Cost: (aver. for district) $0.06 to $0.10 per ton of feed.

Summary. Hand picking, 2-stage concentration in log washers, single-stage treatment of washer fines on shaking tables. No crushing except a small amount of sledging on the grizzlies.

Witherbee, Sherman Co., Mill No. 5 (high-grade ore). Fig. 85. *(Q)*

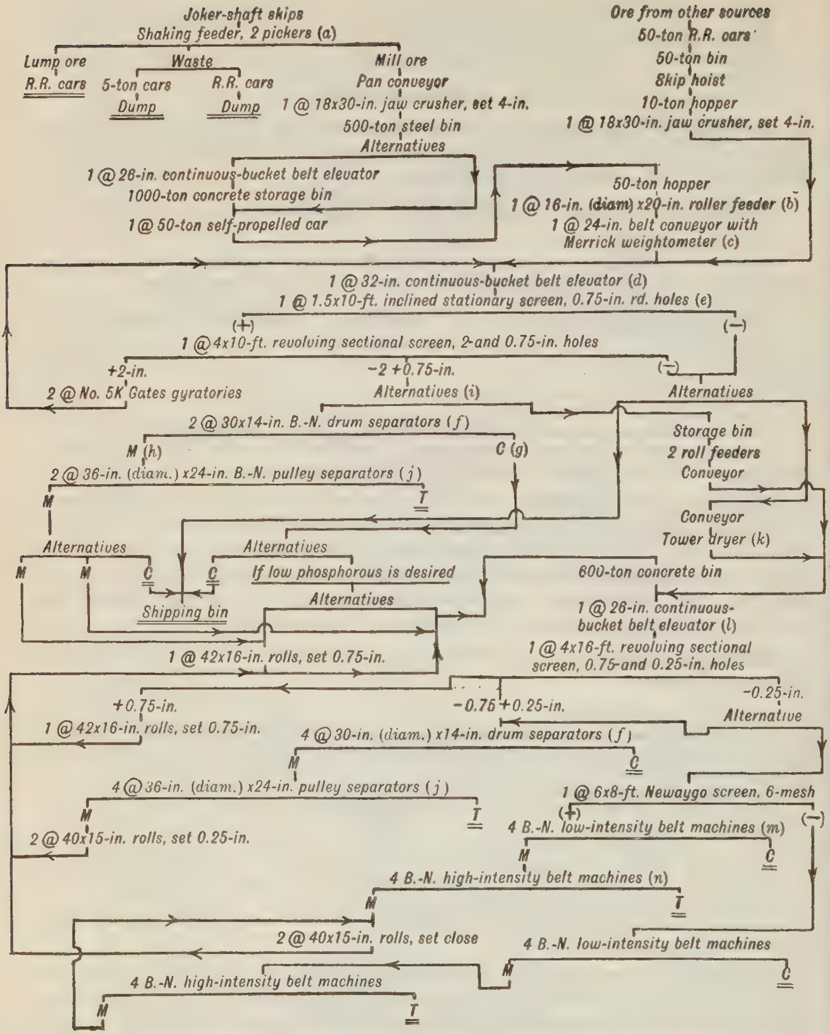
Location: Mineville, N. Y.
Ore: Banded magnetite in gneiss. Analysis: Fe, 49 per cent.; SiO_2, 15.75 per cent; Al_2O_3, 4 per cent; CaO, 8.75 per cent.; MgO 5 per cent.; P, 1 per cent; S, trace.
Capacity: 2000 tons per 24 hr.
Assays: Feed (aver.), 45 per cent. Fe; concentrate, 63 per cent Fe, 0.5 per cent. P; tailing, 6 per cent. Fe.
Recovery: 96 per cent.
Ratio of concentration: 1.4 : 1.
Running time: 90 per cent. of possible.
Power: 5.4 hp.-hr. per ton milled.
Labor: 39 tons per man-shift, operating; 390 tons per man-shift on repairs.
Distances: Mill 500 ft. from shaft mouth; concentrate sold and shipped to various eastern blast furnaces; power transmitted 0.5 mile at 3300 volts.

Summary. Hand sorting and dry magnetic concentration, making concentrate, middling and tailing at all sizes from run-of-mine down. (Compare Mill No. 4.) The magnetic separators for each size are arranged in two stages, low-intensity machines for the first stage, making concentrate and middling for re-treatment on high-intensity machines (second stage) that deliver finished tailing and a middling for re-grinding.

Witherbee, Sherman Co., Mill No. 4 (low-grade ore). Fig. 86. *(Q; 97 J 549; 56 A 899.)*

Location: Mineville, N. Y.
Ore: Banded and disseminated magnetite in gneiss, coarse crystallization. Analysis: Fe, 28 per cent.; SiO_2, 50.5 per cent.; Al_2O_3, 4.75 per cent.; CaO, 3.0 per cent.; MgO, 1.0 per cent.; P, 0.08 per cent.; S, *nil*.
Capacity: 2000 tons per 24 hr.
Assays, per cent. Fe: Feed, 28; concentrate, 64; tailing, 6.8.
Recovery: 84 per cent.
Ratio of concentration: 2.7 : 1.
Power: 8.7 hp.-hr. per ton milled.
Labor: 34 tons per man-shift, operating; 340 tons per man-shift on repairs.
Running time: 80 per cent. of possible.
Distances: Mill at tunnel mouth. Concentrate sold to eastern blast furnaces; power transmitted, 0.5 mile at 3300 volts.

Summary. Dry magnetic concentration, rejecting tailing at −2-in. and making concentrate at −0.75-in. CRUSHING: Jaw crusher from 18- to 3.5-in.; gyratory from 4- to 1.5-in.; 4- and 5-stage roll crushing of middling from 2-in. to 0.12-in. CONCENTRATION: Coarsest material divided into middling and tailing on high-intensity pulley machines; medium-coarse material treated on low-intensity drum machines making concentrate and middling; medium-fine material treated on series-type belt machines (low- and high-intensity) making concentrate, tailing and middling; finest material concentrated on parallel-type (low-intensity) belt machines making concentrate and tailing. All middling re-ground before re-concentrating, except that the middling of one low-intensity drum machine in the middling section is divided into tailing and a middling for re-grinding on a high-intensity pulley machine.



a, One man picks lump ore only; the other, lump ore and waste. *b*, Corrugated face, 10 r.p.m. *c*, 250 ft. long; slope, +2 in. per ft.; 330 ft. per min. *d*, 80-ft. lift, 10-ply belt, 350 ft. per min. 30 × 12 × 16-in. buckets. *e*, ⅜-in. steel plate, 40° slope. *f*, 16 poles. 8 amp. @ 125 volts. *g*, 63 per cent. Fe. *h*, 25 per cent. Fe. *i*, Depending upon character of feed. *j*, 24 magnets. 25 amp. @ 125 volts. *k*, See Sec. 18, Art. 3. *l*, Lift, 80 ft. 10-ply belt, 350 ft. per min. 24 × 10 × 14-in buckets. *m*, 12 magnets. 6 amp. @ 125 volts. *n*, 12 magnets. 9 amp. @ 125 volts.

Fe. *i*, 18 per cent. Fe. *j*, See Sec. 3, Table 22. *k*, See Sec. 13, Art. 5. *m*, 12-in. buckets in 2 rows, staggered.

Fig. 86.—Witherbee, Sherman Co., Mill No. 4.

Replogle Steel Co. Fig. 87. (*Q*)

Location: Dover, N. J.
Ore: Magnetite and martite (Fe_2O_3) in gneiss. Fine crystallization.
Capacity: 3360 tons per 24 hr. aver.; 4800 tons maximum.
Assays, per cent. Fe: Feed, 31; concentrate, 60; tailing, 7.5.
Recovery: 87 per cent.
Ratio of concentration: 2.2 : 1.
General: Sloping mill site. Material dry during most of the milling. Note the large number of elevators and conveyors.

Summary. Dry magnetic separation of closely sized grades through 0.12-in. followed by table concentration at −14-mesh of magnetic tailing and re-ground magnetic middling. Crushing: Jaw crusher from 30-in. to 9-in.; jaw crusher from 9- to 3-in; disk crusher from 3- to 2-in.; rolls from 2- to 0.75-in.; disk crushers from 1- to 0.38-in.; rolls from 0.38- to 0.12-in.; rolls from 0.12- to 0.08-in. Concentration: Belt- and drum-type low-intensity separators making concentrate, tailing for gravity concentration and coarse middling for re-grinding and further magnetic treatment. Gravity concentration on sand and slime tables with re-concentration of primary-table middling without re-grinding. Sand tailing is de-slimed and sold for building sand.

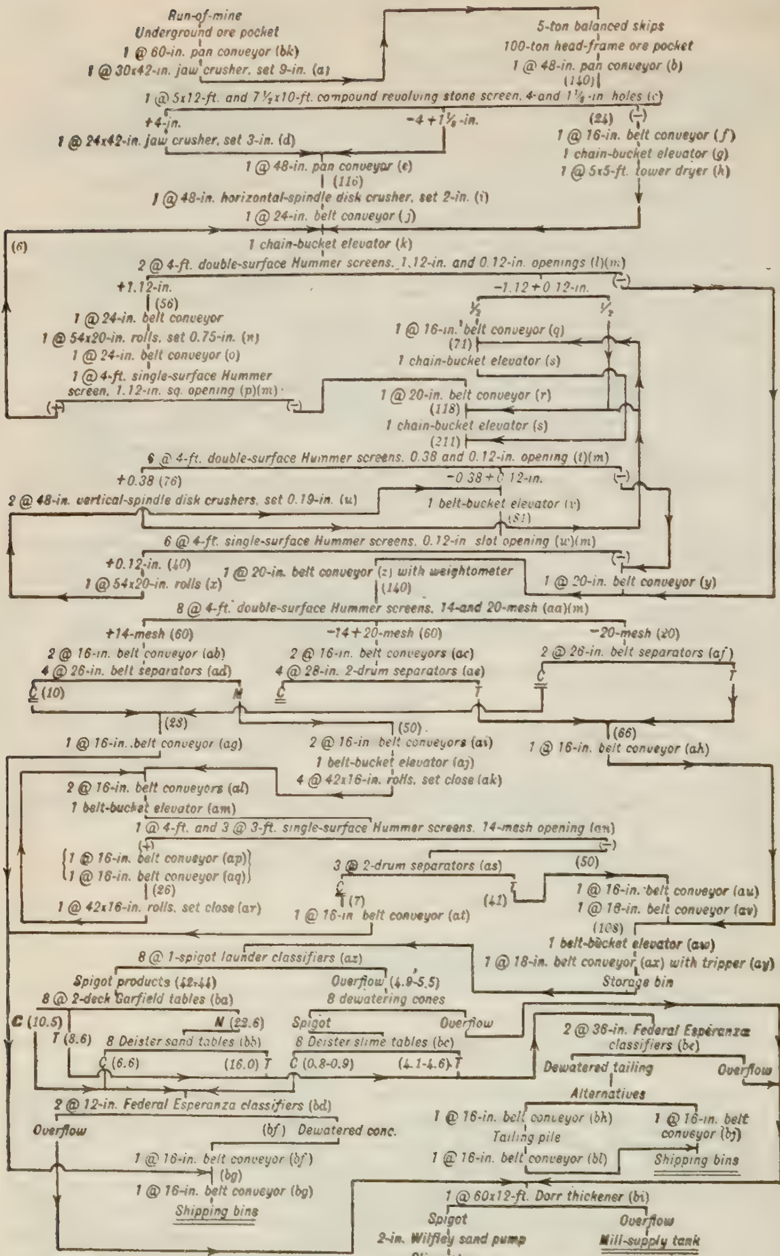

FIG. 87.—Replogle Steel Co.

Fig. 88.—Mesabi Iron Co.

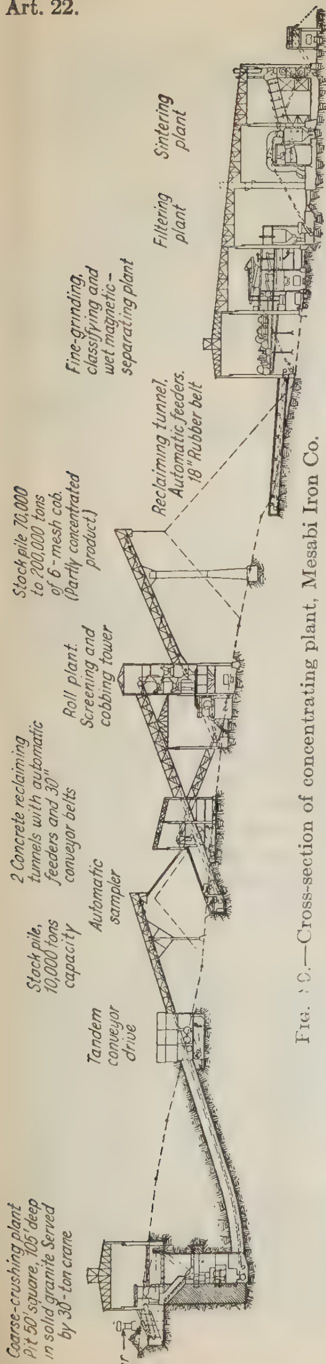

FIG. 89.—Cross-section of concentrating plant, Mesabi Iron Co.

Summary. Step magnetic concentration with rejection of tailing at each step and re-grinding of rough concentrate before cleaning. CRUSHING: Jaw crusher from 48- to 10-in.; jaw crusher from 10- to 5-in.; gyratory from 5- to 2-in.; 2-stage ball-milling, the first stage from −2-in. to 48-mesh, the second from 48- to 150-mesh. Primary mills in closed circuit with 8-ft. duplex Dorr classifiers, the secondary mills in closed circuit with 9-ft. bowl classifiers. CONCENTRATION begins at −2-in. and is carried forward in 3 stages, dry, down to 6-mesh. Minus 6-mesh material is concentrated wet in 3 stages, *viz.:* −6 +48-mesh, −48 +150-mesh and −150-mesh.

Arrangement of machines is shown in Fig. 89. The features of particular interest are the arrangement of the breakers in a rock pit, 50 ft. square by 105 ft. deep; the use of conveyors for all elevation of ore; and the use of stockpiles instead of bins for storage.

Pennsylvania Steel Co. Fig. 90. (*Q*) (1917).

Location: Lebanon, Pa.
Ore: Magnetite with some chalcopyrite and pyrite in silicious gangue.
Capacity: 600 tons per 24 hr.
Assays:

	Fe per cent.	Cu, per cent.	S, per cent.
Feed........	43.7	0.40	1.86
Iron conc....	59.0	0.24	0.9
Copper conc.	36.93	3.66	33.40
Tailing......	14.3	0.36	0.23

Recovery: Fe, 87 per cent.; Cu, 32 per cent.
Ratio of concentration: Fe, 1.55 : 1; Cu, 29 : 1.

Summary. Wet magnetic separation for magnetic iron followed by tabling and flotation for copper.

22. Lead and Zinc

LEAD, Pb

Properties. Metal; bluish-white, soft, plastic, somewhat ductile, not very tenacious. (See also Table 1.) AT. WGT., 207.2. Oxidizes rapidly in moist air, the oxide forming a superficial coating which protects the bulk of the metal. Oxidizes rapidly in dry air, when heated strongly. Pure water containing oxygen reacts with lead to form a slightly soluble hydroxide which thus does not form a protective coating. Impure waters, especially those carry-

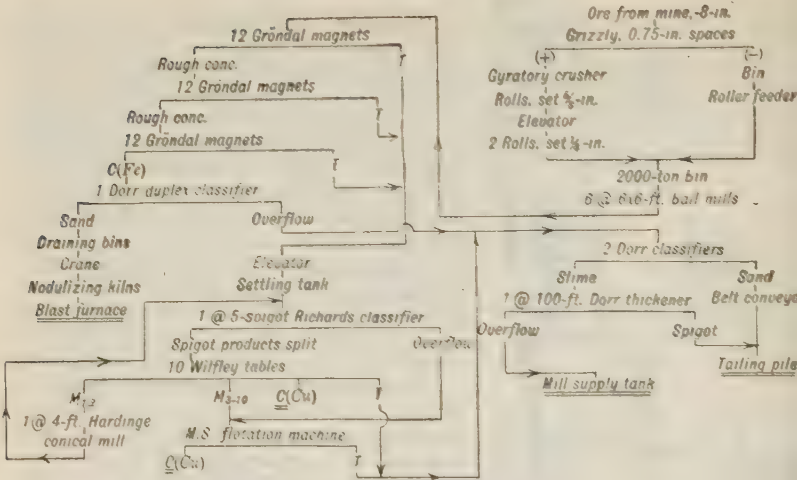

Fig. 90.—Pennsylvania Steel Co.

ing sulphates and carbonates, react superficially, but the corresponding salts, being insoluble, coat the lead and protect it from further action. Hot concentrated hydrochloric, sulphuric and nitric acids attack lead slowly, it combines directly with the halogens and with sulphur. The ion is bi- and quadri-valent, base- and acid-forming. Lead alloys freely with other metals.

Uses. The principal consumption of lead is as the metal and peroxide in storage batteries, as metal in cable coverings and as white lead ($xPbCO_3 \cdot yPb(OH)_2$) in paint. The metal, on account of its non-corrosive properties, also finds wide use for pipes, flashing, etc., in buildings. Considerable metallic lead is used for ammunition making. Important lead alloys are solder, pewter, type-metal, bearing-metal, and various low-fusing metals. The oxides, PbO and Pb_3O_4 are used in glass, rubber and paint manufacture. Lead arsenate is used as an insecticide, but calcium arsenate is more common.

Ores. The economic minerals are galena, cerussite, anglesite and pyromorphite. Galena ores comprise the great majority. There are three general classes: (a) those containing lead alone as an economic metal; (b) lead-zinc

a Range.

ZINC, Zn

Properties. Metal; bluish-white, lustrous. Cast zinc is coarsely crystalline and brittle. When heated to somewhat over 100° C. it becomes soft, tenacious and malleable; it can then be hammered and rolled. Upon cooling, it retains its malleability. This malleable form, when heated to 200 to 300° C. becomes so brittle that it can be crushed to a powder. After such heating the metal retains much of its brittleness on cooling. (See also Table 1.) AT. WGT., 65.4. Oxidizes quickly in air or water at ordinary temperatures. The oxidation products form a protective coating, however, which resists further corrosion. Heated sufficiently in air, zinc burns with a bluish flame. Powdered zinc decomposes water slowly at ordinary temperatures. At red heat zinc decomposes water rapidly. The impure metal of commerce dissolves rapidly in dilute mineral acids. Pure zinc appears insoluble in pure acids, but a trace of the salts of heavy metals starts solution at once. Strong bases attack zinc with the formation of zincates. Zinc ion is always bivalent; it is both acid- and base-forming.

Uses. The important uses are in coating iron to protect it against corrosion (GALVANIZING); BRASS making (zinc, 20–50 per cent.; copper, 80–50 per cent. ± small amounts of tin, lead, and iron); as a constituent of other alloys such as GERMAN SILVER (copper, nickel, zinc) and WHITE METAL (zinc and copper, zinc predominating); in zinc-white pigment; as the positive pole or plate in electrical batteries; zinc shavings and dust in cyanide precipitation; gutters, household utensils, etc., where resistance to corrosion by air and water are desirable.

Ores. The economic minerals are sphalerite, smithsonite, calamine, franklinite, willemite and zincite. There are several distinct types of ores. Argentiferous and auriferous zinc sulphides with or without some lead, copper and iron sulphides in quartzose gangue are typical of the Rocky Mountain deposits. Sphalerite alone or with galena and, usually, with some pyrite

in limestone are typical of the Mississippi Valley deposits. Zinc as franklinite, willemite and zincite in a white, crystalline limestone is the characteristic occurrence in New Jersey. Sulphide ore bodies may be overlain by deposits of smithzonite, calamine and hydrozincite. Such deposits are often more valuable than the primary sulphides, both for the reason that they are more concentrated and that their metallurgical treatment is simpler.

Production in the United States is shown in Table 68. The United States production varies from 40 to 60 per cent. of the world production. Other important sources are Belgium, Great Britain, Germany, Poland, Tasmania, and Canada.

Treatment of lead and zinc ores. From the standpoint of concentration there is a great variety of lead and zinc ores, different in the amount of metal present, the relative proportions of the metals, the character of gangue and fineness of dissemination. Each of these differences has its effect on the type of flow-sheet employed in concentration. Table 70 is a rough classification, embracing the principal ore varieties and naming corresponding concentrating plants whose flow-sheets illustrate methods of treatment. The simple ores, *i.e.*, the sulphide ores of lead, zinc, lead-zinc or lead-silver, coarsely disseminated and with gangues of relatively low specific gravity, are easy to treat. The flow-sheets involve gravity concentration with jigs and tables to recover the bulk of the metallic minerals, followed by collective or differential flotation for the slimes. The complex sulphide ores consist primarily of intergrown lead and zinc sulphides in roughly equal amounts, usually accompanied by pyrite and small amounts of chalcopyrite and other copper sulphides, gold

and silver, in quartz or quartz-calcite gangues. Rhodonite, rhodochrosite, barite and siderite are frequently present. The concentrating problem varies according to the size of the individual grains of galena and sphalerite, and the specific gravity of the gangue minerals. When the sulphides are coarsely disseminated and there are no heavy gangue minerals, treatment consists primarily of selective gravity concentration to collect the bulk of the lead with flotation to catch and in some plants separate the sulphides in the gravity-concentration tailing. In the past iron sulphide has been most successfully separated from blende by magnetic concentration (see NATIONAL ZINC SEPARATING Co. and NORTHERN ORE Co.). At present differential flotation is

a Quartz and siderite. Siderite gangue occurring with blende in the Gennamari and Federal M. and S. ores is classified as having relatively high specific gravity, but compared with galena the specific gravity is low.

highly successful. When there is a heavy gangue mineral such as barite, siderite or rhodonite, it is not possible to make a zinc concentrate by gravity methods. The usual procedure under such circumstances is to take out most of the lead (usually accompanied by the bulk of the silver) by gravity concentration and then either recover the zinc by collective flotation, tabling the flotation concentrate to separate a further amount of lead or, more recently, to use differential flotation. When lead and zinc sulphides occur in very small grains, so that fine grinding is necessary initially to sever them from the gangue and from each other, two general schemes are employed, *viz.:* (1) collective flotation of the sulphides followed by subsequent separation by gravity concentration; (2) selective flotation. Magnetic separation after roasting is practiced to separate iron sulphide from blende, electrostatic separation was

used for many years on fine granular zinc-iron gravity concentrate at the MIDVALE plant of the U. S. S. R. and M. Co., but differential flotation is now almost entirely successful in separating lead, zinc and iron, and will displace the older methods. Oxidized ores are difficult for the reason that differences in specific gravity between valuable and waste minerals are usually less than when the valuable metal is in the sulphide state and simple froth flotation cannot be applied. Mixed, *i.e.*, partially oxidized, ores present the concentrating problems of both sulphide and oxide ores. Normally the method of treatment is to concentrate in stages, first removing unaltered sulphide and throwing oxide into the tailing, then treating this tailing to collect the oxidized values.

Table 71. Typical analyses of southeastern-Missouri lead ores. (*After Watt*)

	Usual ore, per cent.	Rich ore, per cent.
Pb	4.32	6.06
SiO_2	4.83	7.40
FeO	6.64	6.10

Ni+Co	Tr.	Tr.
Cu	0.03	0.50
CO_2, by difference	32.79	33.57

Federal Lead Co., Mill No. 4. Fig. 91. (*Q*; *57 A 322*)

Location: Elvins, Mo.

Ore: Essentially galena, rather coarsely disseminated in dolomite. There is some pyrite and a very small amount of sphalerite. See Table 71. Galena particles are generally less than ¼-in.; much is less than ⅛-in., some very small. 3-mm. crushing will free 90 to 95 per cent. of the total galena, 2-mm. crushing is practically the economic limit (with 4-cent lead), and at 0.21-mm. (65-mesh) substantially 100 per cent. is free. 10-mm. jig tailing assays about 0.6 to 0.8 per cent. Pb.

Capacity: 3000 tons per 24 hr.

Assays per cent. Pb: Feed, 4.75; concentrate, gravity, 75; flotation, 55; tailing, 0.75.

Recovery: 85 per cent.

Ratio of concentration: 18.5 : 1.

Labor: 37 tons per man-shift, total.

Power: 13.9 hp.-hr. per ton milled. See motor list, Table 72.

Water: 7 tons per milled. 85 per cent. of this re-used.

Running time: about 90 per cent. of possible.

Distances: Mill at mine; mill to smelter, 100 miles; water pumped, 1000 ft.; electric power transmitted 1¼ mile at 6600 volts.

General: Gently sloping mill site.

Summary. CRUSHING: Gyratory from 12- to 3-in.; disk crusher from 3- to 0.4-in.; rolls in closed circuit with screens from 0.88- to 0.4-in.; rolls, rod mills and ball mills in parallel, in closed circuit with screens from 0.4- to 0.08-in. CONCENTRATION: Jigging and tabling of primary ore, making tailing and concentrate; jigging and tabling of re-ground middling; flotation (combination routing) of primary and secondary slimes.

The principle underlying this flow-sheet is to crush the galena particles as little as is consonant with the requirement to free them from the gangue. This because gravity concentrate is 10 to 20 per cent. higher grade than flotation concentrate, is cheaper to handle and dry and cheaper to smelt. On account of the large difference in specific gravity between galena and the dolomite gangue, the range in allowable size of jig feed is large, hydraulic classification is unnecessary prior to tabling and only the slime need be removed. The variety of machines in re-grinding, tabling, and in secondary-flotation service is significant only of a progressive experimental turn on the part of the management.

This plant is typical of south-east Missouri lead mills. Minor variations in machines and arrangement are, of course, met, and one or two considerable

differences, such as large jaw crushers ahead of the gyratories at one or two of the plants, and relatively extensive hand picking at MINE LAMOTTE. The primary jaw crushers, where used, are expedients to increase capacity of the crushing plants coincidently with the increase in concentrating capacity effected by flotation. At MINE LAMOTTE the galena is deposited along fractures in a shattered dolomite and is, therefore, less finely disseminated

200	14.0	Trace	16.2	1.6
−200	86.0	100 *a*	83.8	98.4*a*

a 95 per cent. of the lead is −300 mesh.

Chemical analysis, per cent: Pb, 3.0 (usual range is 2.5 to 6 per cent. 5 per cent. at Federal No. 4); Fe, 4.6; Zn, 0.2 (may run to 0.5 per cent. or even higher); Cu, 0.05; SiO_2, 9.0; CaO, 26.0.; MgO, 14.0; Al_2O_3, 4.0; Co, Ni, Trace.

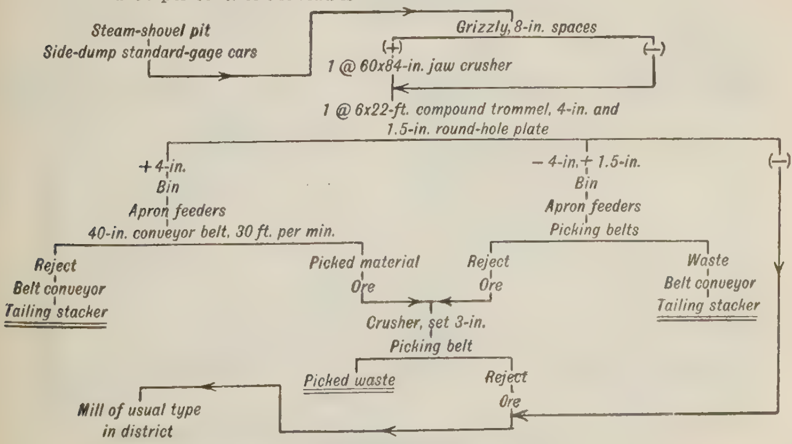

FIG. 92.—Crushing and hand-picking plant at Mine La Motte.

than at the other mines in the district. Further, the deposit lies near enough to the surface to permit steam-shovel mining. A sketch of the coarse-crushing and picking flow-sheet is shown in Fig. 92.

American Zinc Co. of Tennessee. Fig. 93. (*Q*; *118 J 407*.)

Location: Mascot, Tenn.

Ore: Sphalerite in brecciated dolomite. Analysis: calcite, 48.11 per cent.; dolomite, 35.36 per cent.; silica, 8.73 per cent.; alumina, 1.04 per cent.; Fe_2O_3, 1.33 per cent.; sphalerite, 5.43 per cent.

Capacity: 2400 tons per 24 hr.

Assays, per cent. Zn: Feed, 3.4 to 3.8; jig concentrate (about 25 per cent. of total concentrate), 60.8; flotation concentrate, 60.6; jig tailing, 0.7 to 0.85; flotation tailing, 0.09.

Recovery: In flotation, 98.1 per cent. Total recovery on above ore, 86.3 per cent. Total recovery on low-grade ore, about 50 per cent.

Ratio of concentration: 20 : 1.

Distances: Mill at No. 1 (low-grade) mine, 2000 ft. from No. 2 (principal) mine. Mill to smelter, 550 miles; water pumped about 350 ft. from creek; power transmitted 150 miles at 66,000 volts.

Costs, per ton milled: Crushing and jigging, \$0.32; flotation, \$0.08 (\$0.25 per ton floated); drying concentrate, \$0.04 (\$0.80 per ton of concentrate). (1925).

Summary. Jigging and flotation. CRUSHING: gyratory from 14- to 4-in.; disk crusher from 4- to 1.3-in.; rolls in closed circuit with screens from 1.3- to 0.62-in.; rolls in closed circuit with screens from 0.62- to 0.25-in.; ball and tube mills, 1-stage closed-circuit to 65-mesh. CONCENTRATION: Roughing and cleaning of $-\frac{5}{8}$-in. unsized primary feed on hutch-making jigs, both concentrate and tailing made; re-crushed ($1\frac{1}{4}$-in.) middling similarly roughed and cleaned, making concentrate and a tailing that is re-ground and floated in mechanical machines with combination routing. Coarse, sized tailing sold for ballast and concrete aggregate; fine tailing ground for agricultural limestone.

This flow-sheet is influenced by the commercial value of the coarse tailing and the fact that jigging equipment was already operating in a gravity-concentration mill when flotation became successful. Originally concentration was done by jigs and tables only, then flotation was added as an accessory. Within the last few years the hydraulic classifiers and tables (60 to 70 in all) have been dropped and it is a close question whether jigging also would not be eliminated were it not for the fact that the market value of the coarse tailing is greater than the value of the zinc (14 to 16 lb. per ton) at present therein.

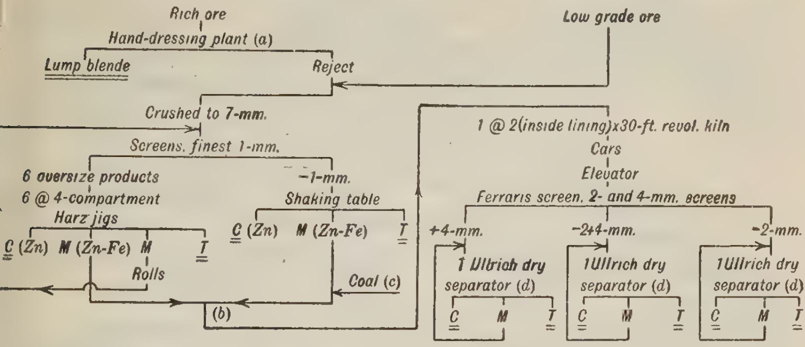
Gennamari-Ingurtosu mine. Fig. 94. *(100 J 911.)*

Location: Ingurtosu, Sardinia, Italy.
Ore: Blende in siderite, quartz, calcite, barite and schist. Coarse dissemination.

Assays: Feed, 10 to 15 per cent. Zn; magnetic concentrate, 53 per cent. Zn and 5 per cent. Fe; magnetic tailing, 2.5 per cent. Zn and 48 per cent. Fe.
Recovery: Magnetic plant, 96 per cent. Zn.



a, Cobbing, hand sorting, hand jigging. *b,* 25 to 35 per cent. Zn and 30 to 40 per cent. Fe. *c,* 10 per cent. by weight. *d,* 1.5 hp. for driving and 10 amp. at 125 volts for energizing.

FIG. 94.—Gennamari-Ingurtosu mill.

Eagle-Picher Lead Co. Netta mill. Fig. 95. (*105 J 727.*) This mill is typical of a large, modern Joplin plant.

Location: Picher, Okla.
Ore: Blende with varying amounts of galena and small amounts of marcasite and chalcopyrite in a chert gangue with varying amounts of limestone, shale and clay. The ores of the district vary considerably in lead content and in the fineness of dissemination of the sulphide minerals, but in most of the ores galena is distinctly less in quantity than blende and both minerals are coarsely disseminated.
Capacity: 1500 tons per 24 hr.
Assays: Feed ranges from 1.5 to 3.5 per cent. Zn with lead content varying from 10 to 50 per cent. of the zinc content. Average analysis of zinc concentrate (*107 J 558*) is Zn, 58.6 per cent; Fe, 1.6 per cent.; Pb, 1.0 per cent.; CaO, 0.9 per cent.; SiO_2, 5.2 per cent; tailing, 0.5 per cent. Zn; 0.1 per cent. Pb.
Costs (pre-war): about $0.25 per ton milled.
At the 1200-ton mill of the AMERICAN ZINC Co. at Joplin (*108 P 840*) in 1914, using jigs and tables only, the recovery was 68 to 69 per cent. and the cost $0.18 per ton, including $0.0275 for elevating and disposing of tailing.

Summary. Jigging, tabling, flotation. CRUSHING: Jaw crusher from 12- to 1.5-in.; 2-stage roll crushing from 2- to 0.38-in.; 2-stage roll crushing of middling with intermediate jigging from 0.38- to 0.08-in.; re-grinding −2-mm. material to 65-mesh in ball mill in closed circuit with Allen cones. CONCENTRATION: Roughing and cleaning jigs on −0.38-in. +0.06-in. feed, roughing and cleaning jigs on −0.25-in. re-ground middling, tabling of classified sands down to 65-mesh and of −65-mesh slimes, separate rougher-cleaner flotation of primary slimes and re-ground middling.

Notes to Fig. 95.

a, 1 James and 6 Butchart. *b,* Usual grade, 10 to 25 per cent. Zn. Some bed product shoveled from first two or three sieves is sent with this. *c,* This screen is omitted in many mills and unsized feed sent to the roughing jig. *d,* Use of a middling jig is unusual in the district; re-ground middling is ordinarily returned to the roughing jig, but as this material is about twice as rich as the original feed, the middling jig is good practice. *e,* Ferraris-type wet shaking screen (*93 J 461*). *f,* Hardwood creosote. *g,* At mills that cannot make substantially lead-free flotation feed, flotation concentrate is tabled to separate lead and zinc.

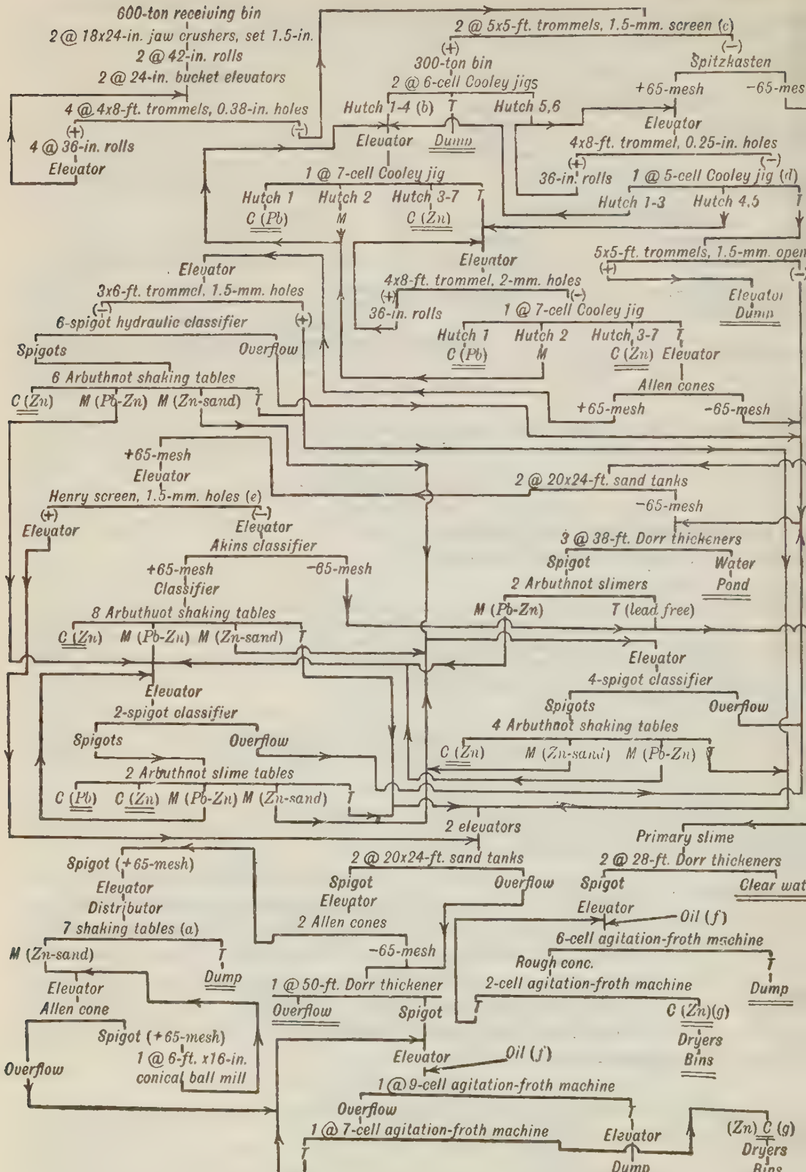


FIG. 95.—Eagle-Picher Lead Co., Netta mill.

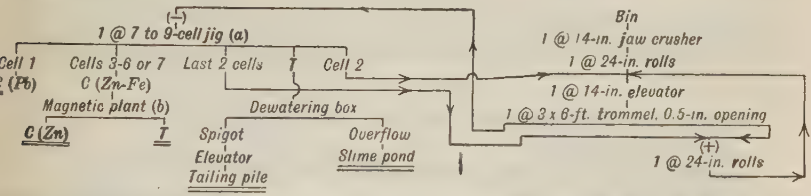
Wisconsin zinc district, one-jig mills. Fig. 96. (*95 J 785; 59 A 117.*)

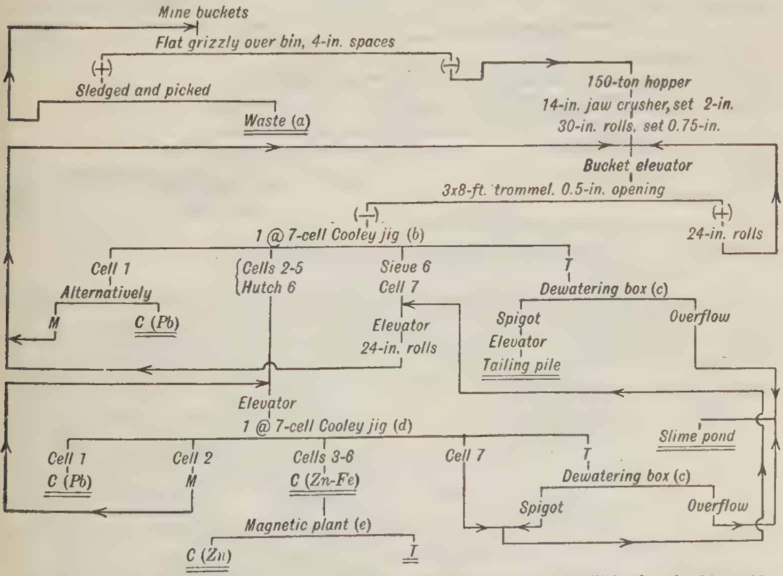
Ore: Galena, sphalerite, marcasite and pyrite in gangue of dolomite, calcite and barite.
Capacity: 100 to 150 tons per 10 hr.
General: This type of mill is applicable only to low-grade coarsely-disseminated ores having a high iron-zinc ratio and not much lead. With such ores much of the lead is recovered in a salable concentrate, and from 60 to 80 per cent. of the zinc in a zinc-iron concentrate assaying 20 to 40 or 45 per cent. Zn. This product is sold to the plants with magnetic separators. (See NATIONAL ZINC SEPARATING Co., p. 164.) If lead content of feed is relatively high, too much lead goes into the zinc concentrate and a 2-jig mill (*q.v.*) must be used.



a, 30 × 36-in. sieves. 200 r.p.m. Concentrate drawn continuously from hutches and shoveled from sieves at the discretion of the operator. *b,* See NATIONAL ZINC SEPARATING Co.

FIG. 96.—Typical Wisconsin one-jig mill.

Wisconsin zinc district, 2-jig mill. Fig. 97. (*59 A 117; 111 J 1065; TP 95 USBM.*)



a, Assay about 0.5 per cent. Zn. Amounts to 5 to 25 per cent. of mill feed. *b,* 30 × 42-in. sieves. *c,* On end of jig. *d,* 28 × 42-in. sieves. *e,* See following flow-sheet.

FIG. 97.—Typical Wisconsin two-jig zinc mill.

Ore: Galena, sphalerite, marcasite and pyrite in dolomite, calcite and barite. Coarse dissemination.
Capacity: 100 to 150 tons per 10-hr. shift.
Assays: Feed, 6 to 8 per cent. Zn; concentrate, unroasted, see Table 75; roasted, 59 to 61.5 per cent. Zn; tailing, 1.5 to 2 per cent. Zn.

Table 75. Analyses of mill (unroasted) concentrate, Wisconsin zinc district. (*After Deutman, 107 J 1108*)

Mine	Per cent. weight				
	Zn	Fe	Pb	CaO	S
Yewdall	21.60	27.40	0.82	2.15	41.60
Martin	39.95	17.12	0.20	1.67	38.30
Jefferson	45.90	12.85	0.22	1.50	35.73

Recovery: 65 to 80 per cent.

General: Tables are not used on account of the high iron and lime contents in table concentrate and the low recovery.

National Zinc Separating Co. Fig. 98. (*107 J 1107.*)

Location: Cuba City, Wis.

Ore: Zinc-iron concentrate from Wisconsin-district zinc mills.

Capacity: 275 tons per 24 hr.

Assays: Feed, 20 to 45 per cent. Zn; concentrate, 59 to 61.5 per cent. Zn; tailing, 4 to 5 per cent. Zn.

Costs: Roasting and separating, $1.28; Cottrell precipitator, $0.18; receiving and shipping, $0.91; general, $0.63; total, $3 per ton of roaster feed.

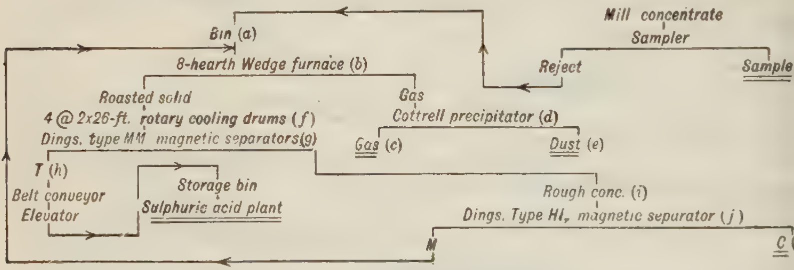


Fig. 98.—National Zinc Separating Co.

a, Separate compartments for concentrates from different mines. *b,* 22½-ft. diameter. 1 drying hearth and 7 for roasting. No fuel added. Maximum temperature at seventh hearth, 900° to 1000° F. Surface of marcasite oxidized to Fe_3O_4. Decrepitation during roasting (see Table 76) causes a decrease in CaO content through dusting. Linden Zinc Co., Linden, Wis., and Wisconsin Zinc Co., Cuba City, Wis., use an oil-fired rotary kiln on the ground that the degree of roasting can be better regulated. *c,* 4 to 5 per cent. SO_2. *d,* 2 units, can be operated together, but ordinarily operated separately and alternately for 2-week periods. Feed about 9000 cu. ft. of gas per min. at 290° F.; velocity, 6 ft. per sec. 36 collecting electrodes in each unit, made of 12-in. 14-gage steel pipe 15 ft. long. *e,* About 95 to 97 per cent. of total roasting loss. Comprises about 1.6 per cent. of solid feed to furnace. *f,* 6 r.p.m. Shells 5/16-in. riveted steel plate. Water-cooled by outside spray. 30 gal. water per min. per machine. Ore not completely cooled, as it is not then so magnetic as when slightly warm to the hand. *g,* See Sec. 13, Art. 8. Campbell, Wetherill and Knowles magnets used in other plants

Table 76. Screen analyses of feed and product of zinc-concentrate roaster

Size	Weight, per cent.	
	Feed	Product
+0.25-in.	0.20	0.10
0.12-in.	21.70	9.70
10-mesh	17.90	7.80
20-mesh	28.10	23.30
40-mesh	22.90	29.10
−40-mesh	9.20	30.00

in district. First poles draw 2 amp. at 225 volts; second, 3 amps. at 225 volts. Air gap of secondary magnets to shaking tray, ⅜ to ½ in. Capacity, 60 tons per 24 hr. *h,* Magnetic product. Averages 25 per cent. S and 4 to 5 per cent. Zn. *i,* 56 to 58 per cent. Zn and 4 to 5 per cent. Fe. *j,* 2 @ 12-in. feed belts, 70 ft. per min. 4 magnets in series drawing 7½ to 15 amp. Capacity, 40 to 45 tons per 24 hr. *k,* 61.5 per cent. Zn.

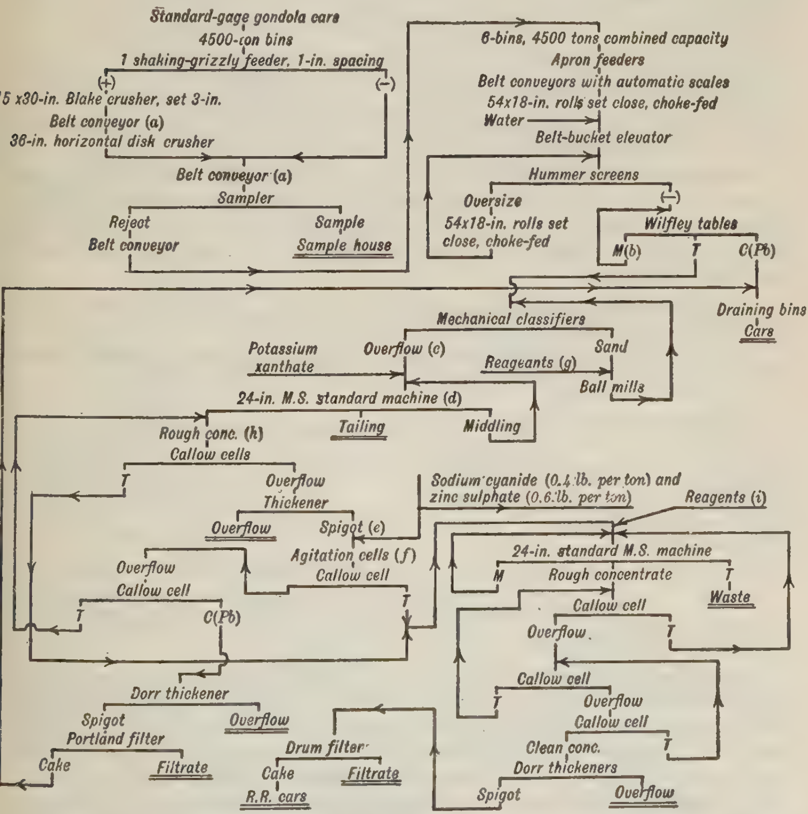
Summary. Roasting and magnetic separation.

Timber Butte Milling Co. Fig. 99. (*Q; 52 A 915; 120 J 685.*)

Location: Butte, Mont.

Ore: Sphalerite, galena, pyrite, bornite, chalcocite, tennantite, tetrahedrite, silver and some gold in quartzitic gangue containing also barite, fluorite, rhodonite and rhodochrosite. Galena is intimately mixed with blende. Considerable iron is combined with the zinc.

Capacity: 800 to 1200 tons per 24 hr.



a, Magnetic head pulley and suspended magnet. *b,* Large circulating load maintained. *c,* 60- to 100-mesh, according to the ore. *d,* Arranged for quick removal of froth. *e,* 50 per cent. moisture or less. *f,* Two in series. Pulp heated to 140° F. and held about one hour. *g,* Lime, 3 lb. per ton; Barrett No. 4, 0.20 lb. per ton. *h,* Pb, 25 per cent.; Zn, 36 per cent.; Fe, 4.0 per cent.; insol., 15 per cent. *i,* Copper sulphate, 1.3 lb. per ton; NaOH, 1.0 lb.; pine oil, 0.06 lb.; Barrett No. 634, 1.5 lb. per ton.

Fig. 99.—Timber Butte mill.

Assays: See Table 77.
Recovery: See Table 77.

Table 77. Performance at Timber Butte mill on Elm Orlu ore with differential flotation. (*After Robie*)

General: Mine to mill, 13 miles. Copper smelter, Anaconda, Mont.; zinc smelter, Bartlesville, Okla.; lead smelter, Midvale, Utah. Water pumped 2 miles. Power transmitted 175 miles at 100,000 volts. Steep sloping mill site. An inclined tramway, 10-ton capacity, 37-hp. hoist, runs alongside the mill, serving all levels. Coarse-crushing plant and concentrate-handling plants are on the lowest level.

Summary. Four-step crushing in jaw crushers, disk crusher and rolls to pass 1/8-in. screen. Table lead concentrate made at this size. Balance ground in one step to 60- or 100-mesh, collective lead-zinc froth made and separated into lead and zinc concentrate by differential flotation with cyanide and zinc sulphate.

Consolidated Mining and Smelting Co. of Canada. Fig. 100. (*116 J 453.*)

Location: Kimberly, B. C.
Ore: Principally galena, marmatite, pyrite and pyrrhotite, with a small amount of quartz and calcite. Brittle, grinds readily. Sulphides intimately associated.
Capacity: 3000 tons per 24 hr.
Assays.

	Pb, per cent.	Zn, per cent.	Ag, oz.	Fe, per cent.	S, per cent.	Insol., per cent.
Feed	10–11	12–13	3	32–33	30–32	4–6

Zinc concentrate	4	40+	....	....	....	....
Tailing *	1.8	2.7	....	....	....	....

* These are the tailing assays in the pilot plant.

Distance: mine to mill, 3.5 miles.

Summary. Differential flotation with tabling of the lead-zinc froth from the early cells of the zinc-flotation machines. CRUSHING: Jaw crusher from 36- to 8-in.; gyratory from 8- to 2.5-in.; rolls from 2.5- to 1-in.; rolls from 1- in. to 0.5-in.; 2-stage ball milling from 0.5-in. to 95 per cent. −200-mesh. CONCENTRATION: Primary lead flotation with 3-stage cleaning of lead concentrate: zinc flotation of lead-machine tailing making finished zinc concentrate; zinc-lead middling, which is tabled for zinc making a lead-iron concentrate that is returned to lead flotation and zinc middling; zinc middling which joins the table-zinc middling and is re-ground and re-floated in a secondary zinc-flotation machine; and a tailing which is classified into sand and slime, the sand being re-ground with the zinc middling while the overflow goes to the tailing plant.

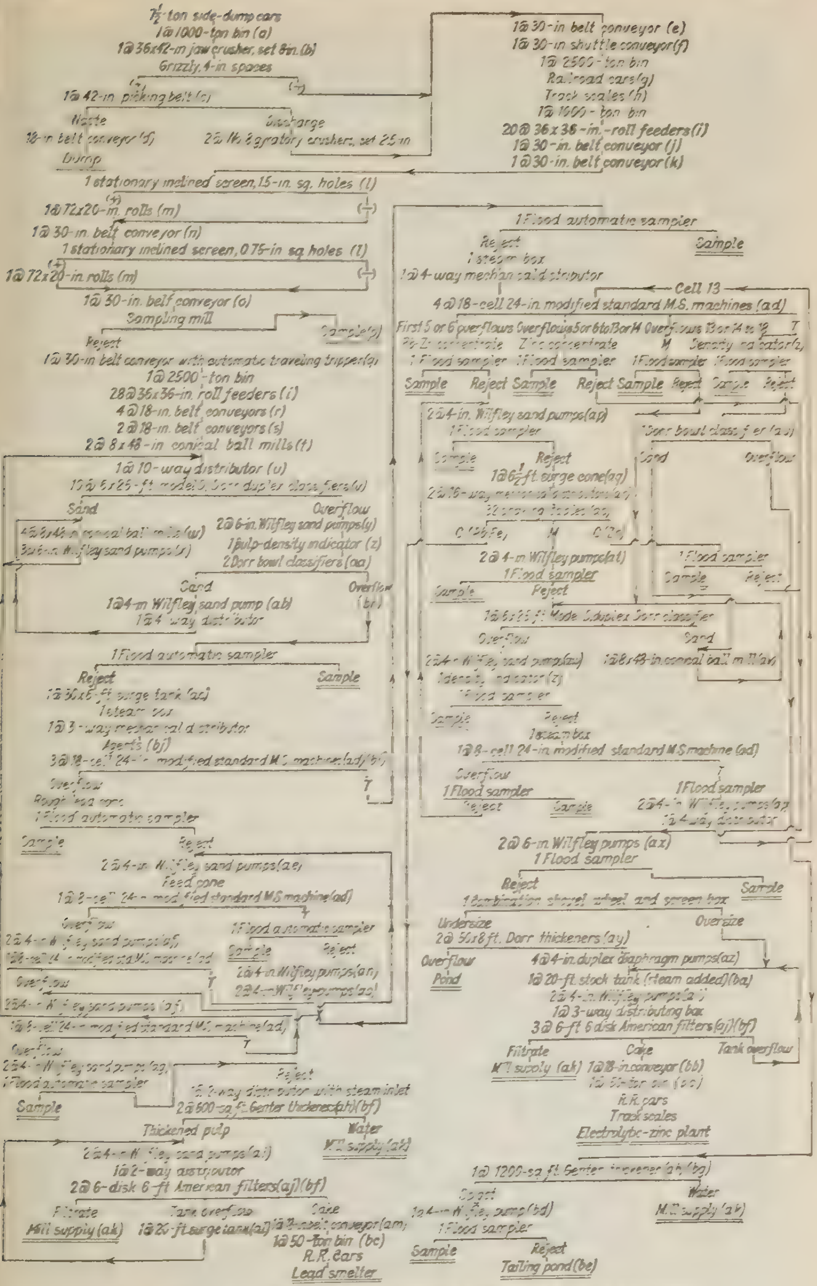

FIG. 109.—Consolidated Mining and Smelting Co. of Canada.

The feature of the plant, other than the outstanding one that it is the first large substantially all-flotation differential mill on this continent, is the complete elimination of bucket elevators by the use of Wilfley sand pumps for all fine wet pulp, and of belt conveyors for dry material and so arranging the machines that no coarse wet material need be elevated. This is distinctly modern practice, and with duplicate pumps, as in this mill, markedly decreases lost time due to breakdown of pulp-transporting equipment. The very complete automatic-sampling equipment is also admirable and should quickly pay for itself in better control of plant operation.

Oil mixture, 3 parts water-gas tar and 2 parts coal tar creosote, 0.5 lb. per ton with 0.1 lb. sodium or potassium cyanide. ***bj,*** Copper sulphate, 1 lb., (0.33 lb. per ton of original flotation feed) and water-gas tar, added at the head of the cells, and 0.05 to 0.1 lb. of a mixture of 9 parts water-gas tar and 1 part coal-tar creosote is added at the 13th cell.

Northern Ore Co. *(116 J 401.)*

Location: Edwards, N. Y.

Ore: Ferriferous sphalerite (black jack) and pyrite with a little galena, pyrrhotite and chalcopyrite in a gangue chiefly diopside, calcite, talc and serpentine. The sphalerite contains about 62 per cent. Zn and 5 per cent. Fe. Analysis of ore: 17 per cent. Zn, 9 per cent. Fe, 17 per cent. S, 0.12 per cent. Pb, 16 per cent. SiO_2, 11 per cent. CaO, 13 per cent. MgO, balance undetermined.

Products: Gravity concentrate, 25 to 30 per cent. Zn, raised to 45 per cent. in the magnetic plant. Jig tailing, 3 per cent. Zn; table and vanner tailing, 1 to 3 per cent.; magnetic tailing, 6 per cent. Zn.

Summary. CRUSHING: Jaw crusher from 8- in. to 2-in.; horizontal disk to about ½-in.; rolls in closed circuit with a trommel to 4-mesh. CONCENTRATION: Material coarser than 8-mesh jigged to make tailing and zinc-iron concentrate. Minus-8-mesh material classified and concentrated on shaking tables and vanners. Middling re-ground in rolls in closed circuit with 12- to 18-mesh Bunker Hill screens and returned to the primary classifier-table circuit. Tailing to waste. Jig and table concentrates are re-ground to −16-mesh by rolls in closed circuit with Bunker Hill screens and treated in a Weatherby high-intensity magnetic separator (Sec. 13, Art. 15) to remove blende.

Fig. 101.—Bunker Hill and Sullivan Mining Co.

Summary. CRUSHING: Gyratory, 10- to 1.25-in.; disk crusher, 1.5- to 0.75-in.; rolls, 1- to 0.5-in.; rolls, 0.6- to 0.25-in.; rolls, 0.3- to 0.15-in.; 2-stage reduction in open-circuit pebble mills to 200-mesh with screening, or classification and concentration intervening between all crushing steps following the disk crusher. CONCENTRATION: Jigging at 4 sizes on primary feed and 3 sizes on re-crushed middling with removal of concentrate and tailing; tabling of −14-mesh sands after classification, making both concentrate and tailing; heavy mineral taken out of slime by vanners; vanner tailing and finest slime floated, combination routing.

This flow-sheet is typically a graded-crushing and graded-concentration scheme with flotation added to clean up the slime, but taking a minor part in the flow-sheet as a whole. Further development is to be expected along the line of elimination of primary hydraulic classification, tabling of unclassified feed, cleaning the rough concentrate on tables, re-grinding all tailing, except, perhaps, that from the coarsest jigs, to flotation size and floating.

Silver King Coalition Mines Co. Fig. 102. (*116 J 369.*)

Location: Park City, Utah.

Ore: Both sulphide and carbonate treated. SULPHIDE: galena with tetrahedrite, pyrite and a little blende in quartz and dolomite. CARBONATE: anglesite and cerussite in the same gangue. About 1000 tons per month of carbonate ore.

Capacity: 300 tons per 24 hr.

Assays:

	Au, oz.	Ag, oz.	Pb, per cent.	Cu, per cent.	Zn, per cent.	Fe, per cent.	SiO_2, per cent.
Sulphide ore:

Concentrate	......	25.5	25.1	0.60	6.0	4.5	32.8
Tailing	0.01	2.0	1.6	......	3.0	1.5	68.0

Recovery: Carbonate ore, 75 per cent. Sulphide ore, without flotation, 85 per cent; with flotation, 90 per cent. (est.).

Ratio of concentration: Sulphide ore, 3 : 1.

Power: 34 hp.-hr. per ton milled.

Costs: About $0.90 per ton milled (1923).

Summary. Gravity concentration by jigs and tables followed by flotation. CRUSHING: Gyratory crusher from 8- to 1.5-in.; rolls from 1.5- to 0.5-in.; ball mills from 0.5-in. to 16-mesh. CONCENTRATION: Jigging of closely sized feed on Harz jigs; tabling of closely classified fine material on shaking tables; sulphide slimes floated in pneumatic cells, rougher-cleaner routing.

Notes to Fig. 102.

Distances: Mine to mill, 2.5-mile tunnel; mill to lead smelter, 260 miles; to zinc smelter, 1500 miles. Water transported one mile by flume. Hydro-electric power from Montana Power Co., 24 miles at 100,000 volts, then 5 miles at 16,500 volts.

General: Sloping mill site.

Summary. Hand sorting, tabling and differential flotation. CRUSHING: Careful graded crushing in jaw and gyratory crushers, rolls, and cylinder mills in closed circuit with screens to 16-mesh. CONCENTRATION: Hand sorting at −6 +2-in. Tabling of −16-mesh sand to make lead concentrate. Middling, re-ground in tube mills, joins primary slimes and is floated in centrifugal and pneumatic bubble-column machines to save lead and zinc differentially.

Central Mine. Fig. 104. (*28 IMM 5.*)

Location: Broken Hill, Australia.

Ore: Galena, low-grade sphalerite and silver in gangue composed principally of quartz, rhodonite, rhodochrosite and garnetiferous sandstone. Minerals are freed at 0.012-in. (0.32-mm.).

Capacity: 600–700 tons per 24 hr.

Assays:

	Ag, oz.	Pb, per cent.	Zn, per cent.	Weight, per cent.
Feed	11.8	14.0	15.6	100.0
Lead concentrate (*a*)	40.8	64.6	9.0	17.4
Lead concentrate (*b*)	39.3	58.1	13.8	1.3
Zinc concentrate	12 8	5.1	47.9	27.2
Tailing	1.3	1.1	1.5	54.1

a From jig and cascade flotation. *b* From sub-aeration machine and Wilfley table.

Recovery, per cent.: Ag, 64.4; Pb, 85.6; Zn, 83.3.

Summary. Jigging for coarse galena (−⅛-in.), differential flotation for bulk of fine galena, collective flotation for zinc and balance of fine galena with separation of collective-flotation concentrate on Wilfley tables.

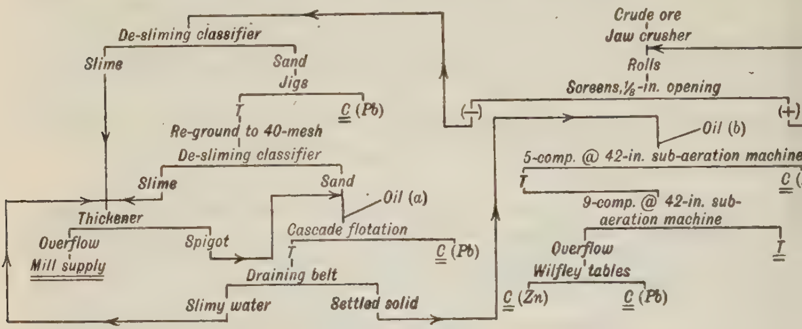
This flow-sheet is a development from another in which, substantially, shaking tables and vanners occupied the place now taken by cascade flotation. Representative results in the older operation are given in Table 82. The selective flow-sheet shows marked

Table 82. Performance of Central mine gravity-and-flotation plant. (*After Harvey*)

Assays	Ag, ounces	Pb, per cent.	Zn, per cent.	Weight, per cent.
Feed	11.6	14.5	16.4	100.0
Lead concentrate (*a*)	32.9	67.6	6.2	15.5
Lead concentrate (*b*)	43.3	60.6	13.8	1.3
Zinc concentrate	16.1	8.3	45.8	30.8
Tailing	2.3	1.8	2.9	52.4
Recovery, per cent.	49.2	77.6	85.8	....

a From primary tables and vanners. *b* From tables treating flotation concentrate.

increase in silver and lead recovery with somewhat lower zinc recovery. The grade of the present lead concentrate is lower, but the zinc concentrate is better. Economic results should be distinctly in favor of the present plant, as the increased recovery of lead and silver, the bettered grade of zinc concentrate, and probable decrease in labor and maintenance should much more than counterbalance the lower grade of lead concentrate and ower zinc recovery.



a, Aver. 0.125 oz. per ton of a mixture of coal tar and eucalyptus oil, varied as necessary.
b, Pine oil and wood-tar oil (and probably sulphuric acid) added as needed.

FIG. 104.—Central mine, Broken Hill.

Roseberry concentrator. Fig. 105. (*114 J 677; 101 J 463.*)

Location: Roseberry, Slocan District, B. C.

Ore: Argentiferous galena and sphalerite with considerable pyrite and siderite in quartz and slate. Silver occurs native and as tetrahedrite, proustite and argentite, very finely disseminated in the galena and blende.

Capacity: 150 tons per 24 hr.

Assays: Surprise ore (1915). Gravity mill only.

	Ag, oz.	Pb, per cent.	Zn, per cent.
Feed	27.7	8.6	19.2
Concentrate, Pb	118.0	62.7	9.7
Concentrate, Zn (*a*)	23.8	3.4	39.0
Tailing (*a*)	5.6	0.3	9.1

a For present flotation concentrate and tailing see Table 83.

Table 83. Flotation results at Roseberry mill. (*After McFadden*)

Ore	Feed			Concentrate			Tailing		
	Ag, oz.	Pb, per cent.	Zn, per cent.	Ag, oz.	Pb, per cent.	Zn, per cent.	Ag, oz.	Pb, per cent.	Zn, per cent.
Bosun	57.7	0.9	12.6	95	2.9	44	1.4	0	0.6

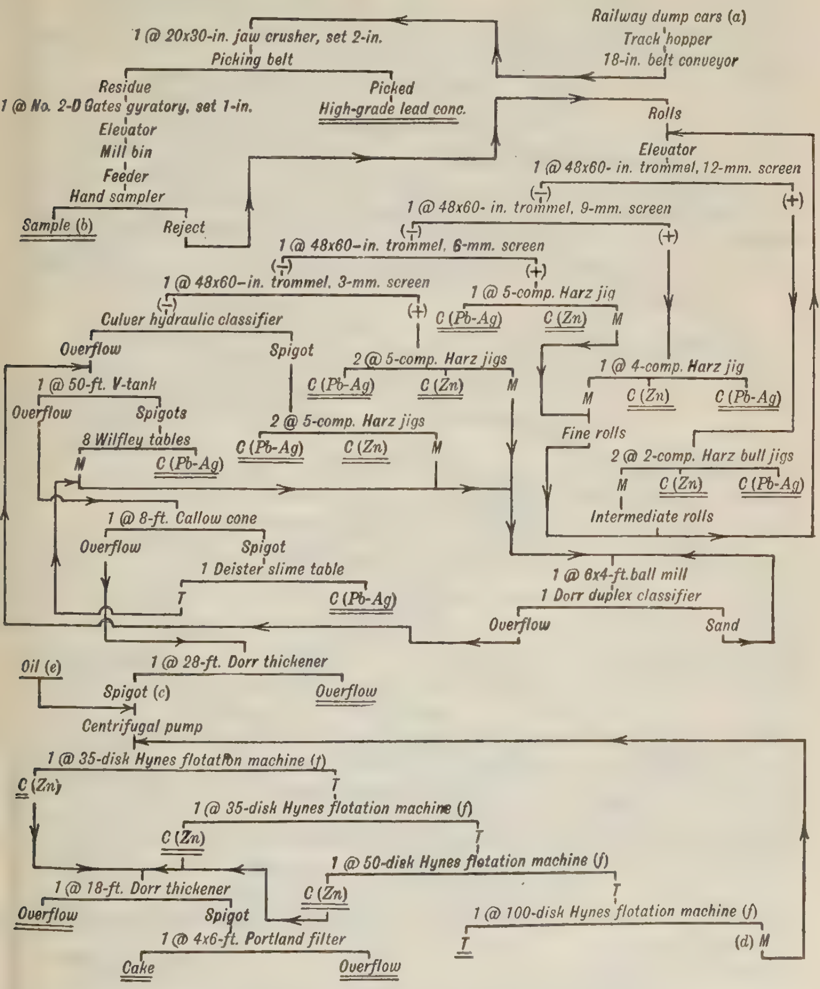
Ivanhoe	12.0	1.1	9.8	45	3.3	45	0.6	0	0.8
Canadian	12.0	1.0	9.6	53	3.9	44.9	0.6	0	0.6

Summary. Gravity concentration by jigs and tables for lead and bulk of silver followed by flotation for zinc and balance of silver. CRUSHING: Jaw crusher, gyratory and 3-stage roll crushing for jigs and tables with re-grinding

of −6-mm. tailing to flotation size in ball mills. CONCENTRATION: 5-stage jigging after sizing and classification with tabling of de-slimed sands. Collective flotation of primary slime and re-ground middling.



a, Gathering from aerial tramways from 4 widely separated mines. *b*, Full stream caught for 30-second period every 15 min. Alternate-interval samples weighed for tonnage. *c*, 30 to 35 per cent. solid. *d*, 10 to 12 per cent. Zn. *e*, 3 or 4 parts water-gas tar to 1 of hardwood creosote. Total oil from 1 to 2 lb. per ton. Some added to machines, if desirable. About 0.75 lb. per ton of copper sulphate. *f*, 30-in. disks of 12-gage plate, 0.5-in. perforations. Rotor speed, 90 r.p.m.

FIG. 105.—Roseberry concentrator.

United States Smelting, Refining and Mining Co., Midvale plant. Fig. 106. (*Q*; 73 *A* 342.)

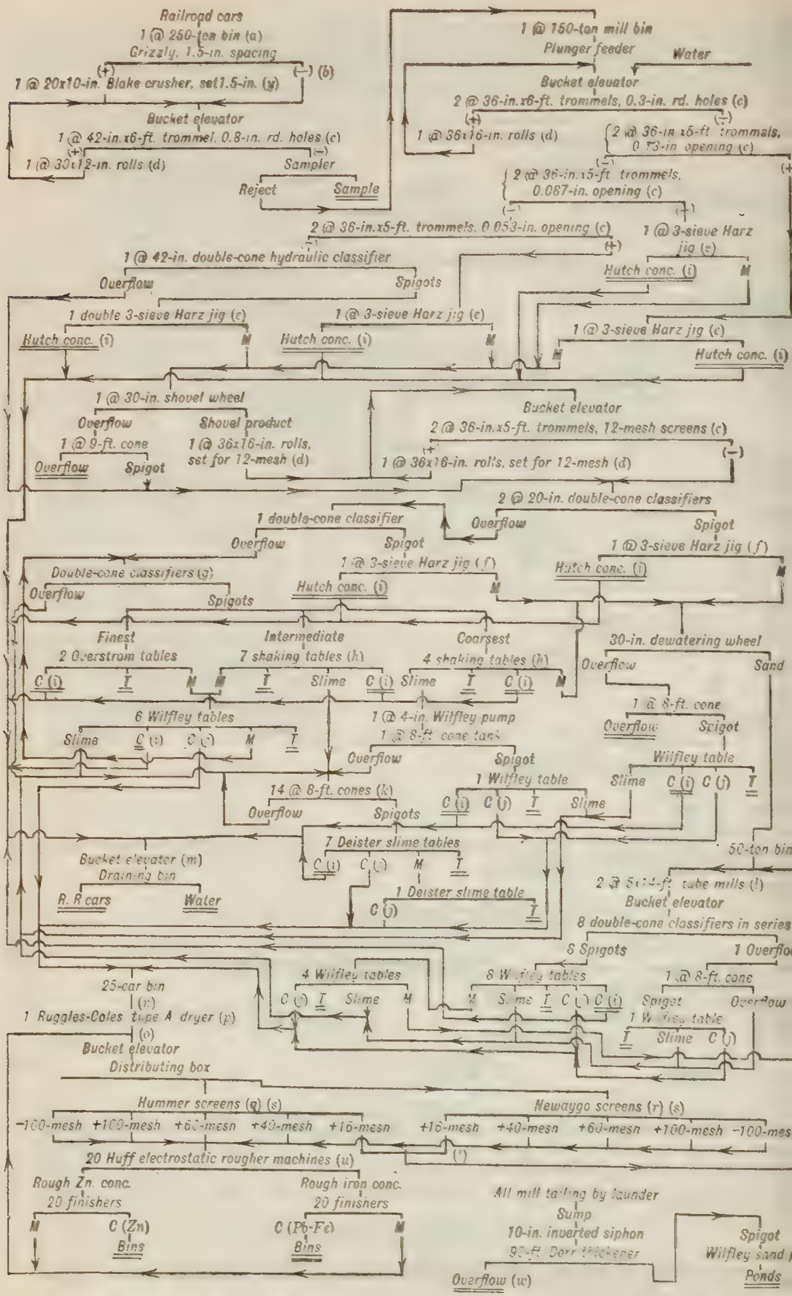


FIG. 106.—United States Smelting, Refining and Mining Co., Midvale plant.

a, Discharged through rack-and-pinion gate, hand operation. *b,* About 25 per cent. *c,* See Sec. 5, Table 26. *d,* See Sec. 3, Table 22. *e,* 36 × 24-in. sieves. Sieve openings larger than largest particle of feed; all concentrate from hutch. See Sec. 9, Art. 3. Bedding replenished by hand as necessary. Continuous spigot discharge from fine jig; intermittent, through manually operated molasses gates, from others. *f,* 24 × 36-in. sieves. See Sec. 9, Art. 3. *g,* A series of these ranging from 30- to 42-in. diameter. *h,* Wilfley and Deister Plat-O. See Sec. 10, Table 1. *i,* Lead-iron. *j,* Zinc-iron. *k,* In series. *l,* About 130 tons per 24 hr. One mill only used except when considerable quartzite is present, when 2 are required. Operated to just liberate mineral and produce as little slime as possible. *m,* Some of the lead-iron conc. cannot reach this elevator by gravity and is manually handled into cars and thence to the R.R. cars. *n,* 12.5 per cent. moisture. *o,* Bone-dry, 280° F. *p,* Capacity, 100 tons per 24 hr., 75-lb. slack coal per ton dried. Forced draft by 45-in. fan to 30-in. × 48-ft. stack. See Sec. 18, Art. 4. *q,* 75 per cent. of feed. Two @ 2-surface screens in series. *r,* 25 per cent. of feed. Two 2-surface screens in series. *s,* Screens: 16-mesh steel, 0.0445-in. sq. opening; 40-mesh brass, 0.014-in. sq. opening; 60-mesh brass, 0.007-in.; 100-mesh brass, 0.0045-in. *t,* About 2 per cent. of screen feed. *u,* 14 Type F consisting of 1 rougher and 2 finishers in each unit. 18 Type D (remodeled), 3 of which are required to make a 1-rougher-2-finisher unit. One 7½-kw. generator direct-connected to 5-hp. motor furnishes electrical energy. Voltage stepped up from 120 at generator to 18,000 to 22,000 at machines. *w,* 55 per cent. of feed tonnage. *y,* See Sec. 3, Table 5.

Location: Midvale, Utah.

Ore: Argentiferous galena, auriferous pyrite, chalcopyrite, and sphalerite in quartz, quartzite, limestone and porphyry. Sulphides range from coarse aggregation to very fine dissemination.

Capacity: 465 tons per 24 hr.

Assays:

	Pb, per cent.	Fe, per cent.	Zn, per cent.	Insol., per cent.	Ag, oz.	Au, oz.
Lead-iron conc. from jigs......	25.0	24.0	10.0	3.5	12.0	0.15
Zinc conc., electrostatic.......	1.8	6.2	49.5	8.2	1.4	0.03
Iron conc., electrostatic.......	4.9	35.0	8.0	2.0	4.5	0.12
Tailing......................	1.7	3.5	5.25	......	1.1	0.02

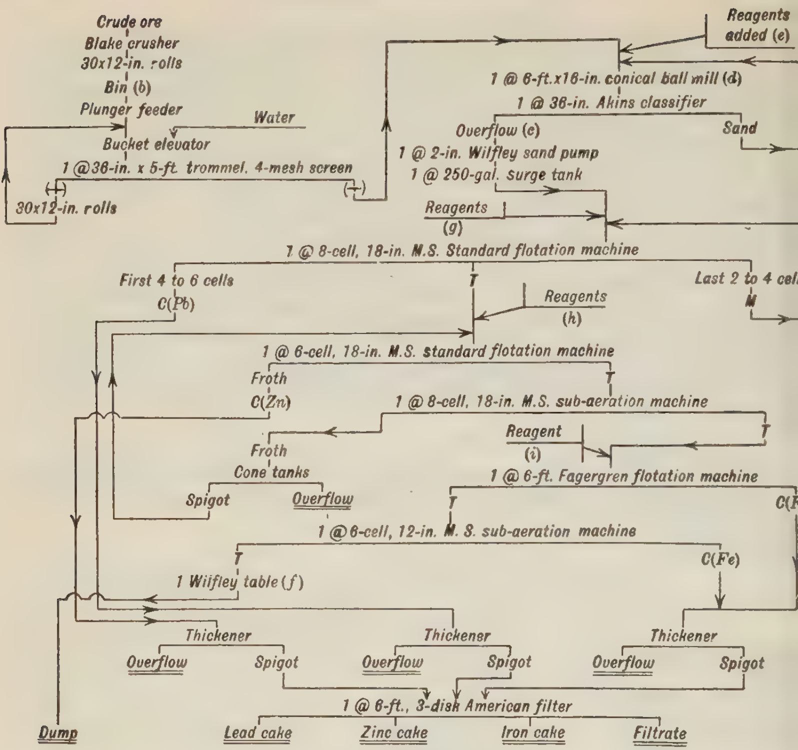
Recovery, per cent.: Pb, 91; Zn, 40; Ag, 87; Au, 87.

General: Distance mine to mill, 18 miles.

Summary. Graded crushing, jigging of sized products and tabling of classified products. Electrostatic separation of zinc-iron table middling. CRUSHING: Jaw crusher, 9- to 1.5-in.; rolls, 1.5- to 0.75-in.; rolls, 0.75- to 0.25-in.; 2 rolls in series, 0.25- in. to 12-mesh; tube mill to 28-mesh, open circuit. Screens precede all crushers. CONCENTRATION: Jigging starts at 0.25-in. with 5 steps down to 12-mesh. Jigs make lead-iron concentrate and a middling only. Tabling starts at about 16-mesh (1-mm.) and continues to the finest sizes. Electrostatic machines treat −16-mesh material in 4 sizes.

This is a relatively complex ore, but the individual mineral grains are sufficiently coarse to permit severing to an economic extent by crushing to about 0.5 mm. and separation of lead from zinc by gravity concentration. Recoveries are satisfactory for this type of ore, except the zinc recovery.

Differential flotation, according to the flow-sheet, Fig. 107, is expected to replace the old flow-sheet. This is an experimental plant running in competition with the regular gravity-concentration and electrostatic plant. Capacity, 50 tons per 24 hr. Recoveries and grades have been satisfactory except with ores containing considerable amounts of oxidized minerals.



b, 0.5 in. *c,* 20 per cent. solid. All −65-mesh, 65 per cent. −200-mesh. *d,* 7500 lb. @ 2½-, 2- and 1½-in. cast-iron balls; consumption, 1.7 lb. per ton crushed. Titanite lining, life 8 mo. *e,* Barrett No. 4 coal-tar creosote or similar oil, steam-distilled pine oil sodium sulphite. On some ores sodium sulphide and sodium silicate are also added here. *f,* Pilot. *g,* Potassium xanthate. Soda ash with some ores. *h,* Pine oil, Barrett No. 4 or similar oil, hardwood creosote, potassium xanthate, copper sulphate. *i,* Sodium sulphide. A small amount of pine oil and Barrett No. 4 with some ores.

A separate leaf of the filter works on each concentrate.

FIG. 107.—Differential flotation plant at U. S. S. R. & M. Co., Midvale plant.

Sunnyside Mining and Milling Co. Fig. 108. *(Q; 105 J 193; 109 J 838; 121 J 757.)*

Location: Eureka, Colo.

Ore: Galena, sphalerite, chalcopyrite, pyrite, silver and gold in quartz-calcite-rhodonite gangue. Sulphides finely disseminated.

Capacity: 750 tons per 24 hr.

Assays:

Recovery:

	Au, per cent.	Ag, per cent.	Pb, per cent.	Cu, per cent.	Zn, per cent.
Lead concentrate	55	50	71	42	13
Zinc concentrate	10	16	11	21	66
Middling	11	11	8	15	9

Labor: 10 tons per man-shift, total.

Water: 4.9 tons per ton milled.

Power: 43 hp.-hr. per ton milled.

Distances: Mine to mill, 3 miles; mill to zinc smelter, 700 miles; mill to lead smelter, 54 miles; water transported, 1 mile by gravity pipe line; power transmitted, 54 miles at 50,000 and 17,000 volts.

Costs, cents per ton (1925):

	Labor	Reagents	Other Supplies	Power	Total
Lead flotation	3	9	1	2	15
Zinc flotation	3	17	....	4	24

Summary. Differential flotation. CRUSHING: Gyratory from 12- to 3-in.; ball mill from 3-in. to 20-mesh; tube mill from 20-mesh to 65-mesh. CONCENTRATION: differential flotation.

In 1925–26 about 15 tons per day of a mixed lead-zinc middling product was made and sold, additional to the regular lead and zinc concentrate. This was made possible by a peculiar local smelting need and enabled the production of higher-grade zinc and lead concentrates than otherwise.

Zinc carbonate ores are relatively rare.

In the Highland, Wis., district (*99 J 906*) small deposits of mixed carbonate and sulphide ore are worked by leasers. The ore is hand picked and the high-grade material stacked on the surface until sufficient has accumulated or until weather conditions are suitable and is then crushed in a set of slow-speed rolls, roughly concentrated in a log washer and cleaned on a power hand jig. The mixed concentrate carries about 40 per cent. Zn. Recovery is, naturally, low, but the deposits are too small to warrant more elaborate equipment. At MONTEPONI, Sardinia (*83 J 1094*) a 500-ton plant treating calamine in dolomite with some zinc, lead and iron sulphides consists of a 4-in. grizzly and a series of shaking screens of 1.25-, 0.8-, 0.55-, 0.4-, 0.28-, 0.2-, 0.12-, and 0.08-in. apertures to prepare feed for a picking belt and a series of jigs. Concentrate and tailing are rejected at all sizes and middling is re-ground and treated by magnetic separation to remove iron.

New Jersey Zinc Co. Franklin mill. Fig. 109. (*Q.*)

Location: Franklin, N. J.

Ore: Willemite, franklinite and zincite together with zinciferous manganese silicates in calcite.

Capacity: 100 tons per hr. (2-shift work).

Assays, per cent. Zn; Feed, 17; concentrate; willemite, 48; franklinite, 17; tailing, 2.25.

Recovery: 93 per cent.

Labor: Tons per man-shift, operating, 8.6; repairs, 179.

Power: 20 hp.-hr. per ton.

Water: 8 tons per ton of ore milled, approximately 99 per cent. recovered.

General: Level mill site. Concentrate shipped 90 miles. Tailing filled back into the mine.

Summary. High-intensity magnetic concentration to collect franklinite; willemite and zincite recovered on jigs and shaking tables. CRUSHING: Careful graded dry crushing in gyratory and rolls to $-\frac{1}{10}$-in. CONCENTRATION: Magnetic concentration follows extremely close dry sizing, coarse-sized non-magnetic material is jigged, fine is carefully classified and tabled.

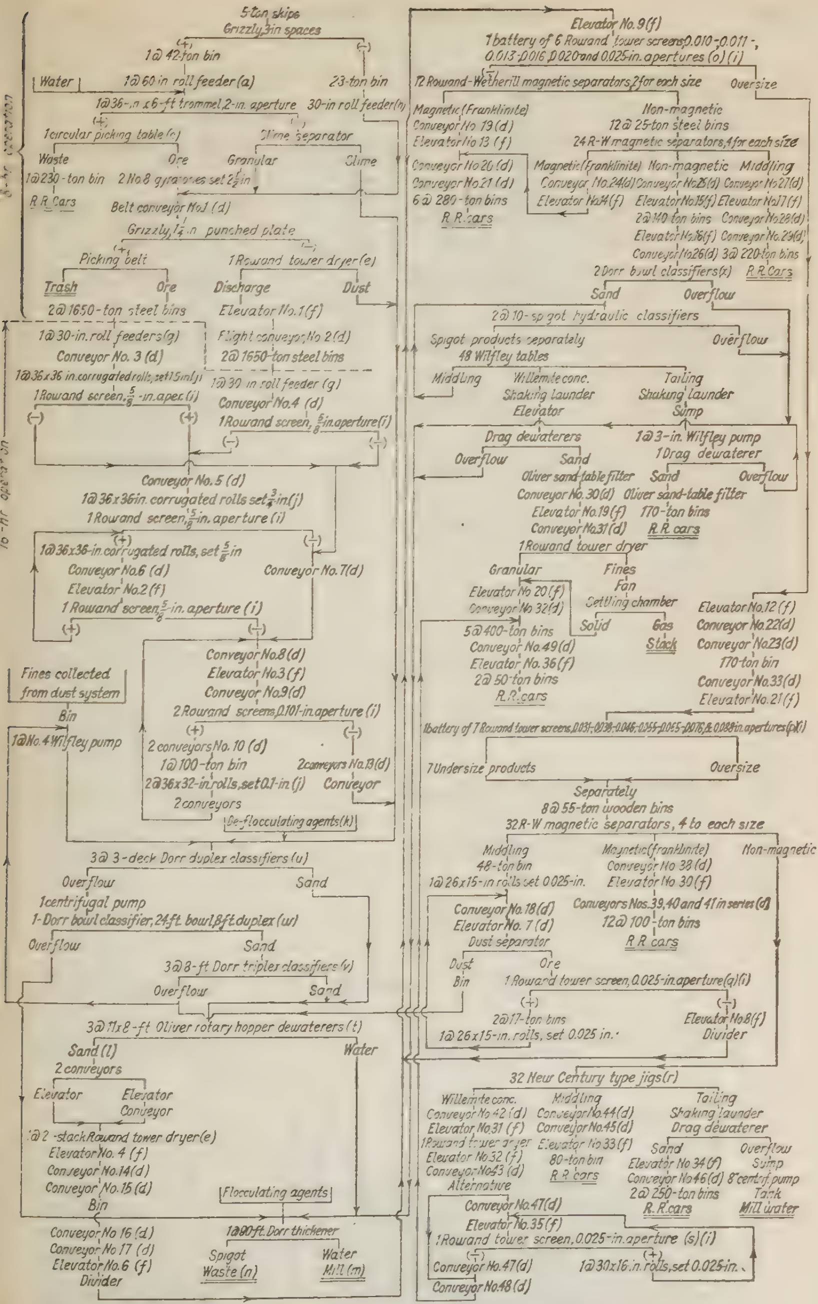

FIG. 109.—New Jersey Zinc Co., Franklin mill. (See p. 188 for notes.)

American Smelters Securities Co. Fig. 110. (*112 J 1050.*)

Location: Santa Barbara, Chihuahua, Mex.

Ore: Lead carbonate with small amounts of gold and silver; silicious gangue with some lime.

Capacity: 500 tons per 24 hr.

Summary. Table concentration after careful hydraulic classification. Compare with Shattuck-Arizona.

Shattuck-Arizona Copper Co. Fig. 111. (*Q; 110 J 759.*)

Location: Bisbee, Ariz.

Ore: Cerussite, cerargyrite, gold and a small amount of lead sulphate (anglesite) in a silicious gangue with some specular hematite and limonite. Sulphur about 0.1 per cent.

Capacity: 400 tons per 24 hr. 500 tons has been handled with but little loss in efficiency.

Assays:

	Au, oz.	Ag, oz.	Pb, per cent.	Fe, per cent.	Insol., per cent.
Feed	0.059	7.22	6.27	13.73	65.99
Concentrate	0.227	28.53	32.92	20.6	22.3
Tailing	0.022	2.52	0.43	....	....

Recovery, per cent.: Au, 69.4; Ag, 71.3; Pb, 94.4.

Ratio of concentration: 5.56 : 1.

Labor: Tons per man-day (24 hr.), operating, 25; repairs, 36.4; total, including outside surface men, 9.1.

Power: 24 to 32 hp.-hr. per ton milled.

Water: 2 to 3 tons fresh water per ton milled.

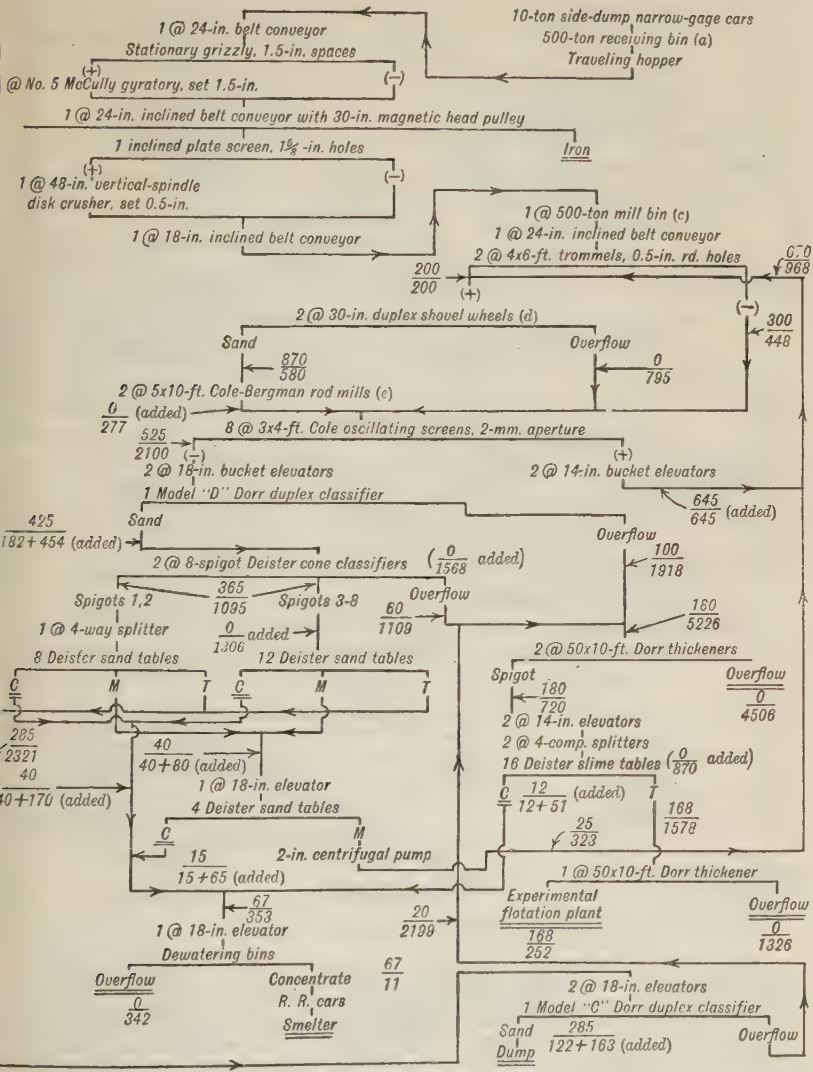
Running time: 76 per cent. of possible. Stoppages due to lack of ore, water and power and to repairs.

Distances: Mine to mill, 3½ miles; mill to smelter, 250 miles; power from a power company; water from adjacent mine and from city (Naco) supply.

General: Sloping mill site with crushers at track level and inclined conveyor to top of mill bin. (See photograph *110 J 760.*)

Summary. Crushing: From run-of-mine to 35-mesh as follows: Gyratory from 8- to 1.5-in.; rolls from 2- to 0.5-in.; ball mills and ball-tube mills respectively grinding −⅝-in. + 4-mesh and −4-mesh to 35-mesh. Concentration: One-stage tabling at −4-mesh, unclassified, and 2-stage tabling at −35-mesh, de-slimed; sulphidizing flotation of slimes by concentrate-middling routing.

This is simple, efficient and comparatively cheap treatment of a difficult ore. It depends for its success on quick and effective surface sulphidizing of the finely ground oxidized



a, Flat bottom, concrete. 8 bottom outlets. *c*, Redwood tank, 30 ft. (diam.) × 24 ft. with hopper and rack-and-pinion gate at center of bottom. *d*, See Sec. 16, Art. 2. *e*, 19.8 r.p.m., 100-hp. motor, Lenix drive.

Fig. 110.—American Smelters Securities Co.

lead and silver minerals. Few oxidized lead-silver ores yield so readily to sulphidizing treatment and, failing this, gravity concentration of the slimes is expensive and inefficient. Another apparently successful method of treatment is practiced at Chief Consolidated Mining Co. (Fig. 113).

Royal Asturiana Mining Co. Fig. 112. (*115 J 395.*)

Location: Reocin, Spain.

Ore: Sphalerite, 15 to 30 per cent.; calamine, 1 to 4 per cent.; galena, 1 to 7 per cent.; iron as oxide and sulphide, 3 to 7 per cent.; gangue practically all dolomite.

Capacity: Crushing plant, 800 tons per 24 hr.; concentrator, 200 tons per 24 hr.

Labor: 11 tons per man-shift, operating.

Power: 24 hp.-hr. per ton.

Water: 7 tons per ton milled. A large part is returned.

Summary. Tables, flotation, tabling of flotation concentrate. CRUSHING: Jaw crusher from 13- to 3-in.; jaw crusher from 3- to 1-in.; ball mill in closed circuit with screen from 1.5-in. to 0.08-in.; ball mill in closed circuit with Dorr classifier from 2-mm. to 0.2-mm. CONCENTRATION: Tables treating de-slimed −2-mm. feed and making lead and zinc concentrate and a tailing for re-grinding and flotation; collective flotation (concentrate-middling routing) with separation of lead and zinc in concentrate by shaking tables.

This flow-sheet was adopted in 1918–19 after careful tests of all-flotation treatment. The combined treatment yielded higher lead recovery, and, when zinc oxides were present, more zinc.

Chief Consolidated Mining Co. Fig. 113. (73 A 200.)

Location: Eureka, Utah.

Ore: Silicious replacements in limestone, carrying gold and sulphide and oxide minerals of lead, silver, iron and zinc.

Capacity: Volatilization plant, 250 tons per 24 hr.; concentrator, 300 tons per 24 hr.; crushing plant, 65 tons per hr.

Assays:

FIG. 112.—Royal Asturiana Mining Co.

re-ground and floated in pneumatic cells with combination routing. Flotation tailing dried and volatilized.

This plant is a pioneer in volatilization of lead-silver-gold ores without addition of volatilizing agents. The process is commendable in principle and the results cited are excellent. Mechanically the plant would appear to be very weak in the large number of bucket elevators and screw conveyors and it is a relatively safe prediction that lost time will be high until these are largely replaced by belt conveyors.

A water-cooled plow is provided to plow out accretions as necessary. Plowing requires about 20 min. Coal about 30 per cent. of furnace feed. *h,* Hot fume does not come in contact with ore. *i,* 20,000 sq. ft. *j,* 42,000 sq. ft. *k,* Capacity sufficient to supply 75 tons powdered coal per 8 hr.

FIG. 113.—Chief Consolidated Mining Co.

23. Manganese, Mn

Properties. Metal; reddish-white, lustrous, hard, slightly magnetic. (See also Table 1.) AT. WGT., 54.9. Only slightly attacked by air when pure. Dissolves readily in acids forming corresponding bi-valent salts. Forms a great diversity of compounds. Ion is bi-, quadri-, sexa- and septa-valent. The lower oxidation products form bases, the higher, acids. Alloys with other elements.

Uses. Manganese is not used commercially in the free state. Its greatest use is in the steel industry where it is introduced in the form of the iron alloys, ferro-manganese or spiegeleisen. Probably the next most important use of manganese is as the dioxide (MnO_2) in the making of dry batteries. This calls for a very high-grade product containing about 80 per cent. MnO_2 and less than 1 per cent. iron. Other uses of manganese compounds are: oxidizing agent in the manufacture of chlorine, bromine, and disinfectants; dryer in paints and varnishes, coloring agent in calico printing and dyeing, in making glass, pottery, brick and paints. Manganese bronze is an alloy with copper which may or may not contain some iron; silver bronze, an alloy with aluminum, zinc, copper and silver; manganese-titanium, an alloy of these metals with iron for use in the manufacture of special steels.

Ores. The economic minerals are pyrolusite, psilomelane, braunite and wad. The specific gravity of the manganese minerals as mined is 3.5 to 5 and averages between 3.5 and 4. These minerals occur as nodules, lumps, pockets, stringers or lenticular masses irregularly scattered through residual clays and weathered rocks. Domestic deposits are small. The common associates, beside the clay, are limonite, barite, ocher and bauxite. Manganiferous iron, manganiferous silver, and manganiferous zinc ores also occur.

Production. Manganese is used in three forms, viz.: high-grade ore (+35 per cent. Mn) for making ferro-manganese and for chemical uses; manganiferous iron ores, containing 10 to 35 per cent. Mn; and iron ores containing 5 to 10 per cent. Mn. Only the first class is concentrated. Production of this class of ore in the United States is confined to the few states named in Table 86. The United States produces only from 1.5 to 3.5 per cent. of the world production. The principal foreign producers are Brazil, British India, Gold Coast, Russia and Georgia, Cuba, China and Spain.

Table 86. Production of high-grade (+35 per cent. Mn) manganese ores in United States (long tons) (a)

State	1921	1922	1923	1924
Arkansas	728	2,264	3,768	8,400
Colorado	490	....	2,278	b
Georgia	....	....	1,502	1,893
Montana	11,129	9,751	21,916	29,445
Virginia	717	800	987	1,565
Washington				5,000
Others (c)	467	589	1,049	10,012
Total	13,531	13,404	31,500	56,315

a USGS. *b* Included under "Others." *c* Ala., Ariz., Cal., Nev., N. M., Tenn., Utah.

Selling. High-grade domestic ore (concentrate) for ferro-manganese is sold on the basis of the content in long-ton units (22.4 lb. per ton) of metallic manganese with a fixed lower limit as to manganese content, frequently between 45 and 50 per cent., and maximum limits of 8 per cent. silica and 0.2 per cent. phosphorus, with premiums for higher manganese and lower silica and phosphorus. Lime in such concentrate is not undesirable, but too much iron is. The ore should be in lump form and hard enough not to crumble in the blast furnace. Chemical ore should contain from 70 to 90 per cent. MnO_2 (it is the available oxygen that is important), and should be low in lime, iron, copper, nickel, cobalt and arsenic, but may contain more phosphorus than the limit for metallurgical ore. Prices in 1924 ranged from \$0.38 to \$0.46 per long-ton unit for metallurgical ore; in the spring of 1926 it was quoted \$0.42 @ \$0.44. At the same time chemical ore, 82 to 87 per cent. MnO_2 was quoted \$70 to \$80 per ton at New York (*Eng. and Min. Jour.-Pr.*). Demand is increasing and the United States is a large importer.

Treatment. The method of concentrating depends upon the character of the ore deposit. When the ore is nodular, in easily disintegrated clay, and the nodules are high-grade, simple washing by log washer or wash trommel is all that is ordinarily necessary.

At EUREKA CC., Batesville, Ark., the ore is washed in a 30-ft., 2-log washer at 20 r.p.m. The log product is sent to a wash trommel (16-mesh), then sized at ½-in. into coarse and fine shipping grades. The washed product contains about 42.5 Mn.

When silicious and other foreign matter occurs in the nodules, a more complicated plant involving crushing is necessary. The CRIMORA mill, Fig. 114, is typical. When the ore occurs in rock, which must be mined with the manganese minerals, the flow-sheet is commonly graded crushing followed by jigging and tabling. The PHILIPSBURG MINING Co. plant is an ingenious departure.

WASH ORES, to be readily amenable to treatment, should carry better than 3 per cent. of manganese mineral. Leaner material can be handled, if it can be graded up by picking, but in general the wash ores average about 10 per cent. manganese content. Some manganese deposits run as high as 25 to 35 per cent. Mn. The character of the clay is important; if tenacious, capacity and grade of product will be much reduced and tailing loss high.

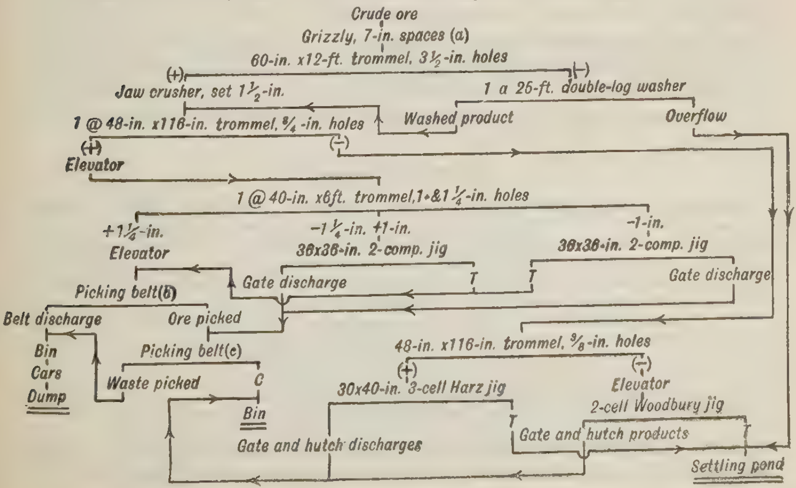
Philipsburg Mining Co. *(Bul. 725 C, USGS 152; Bul. 734 USGS; Bul. 173, USBM 51; 116 J 181.)*

Location: Philipsburg, Mont.
Capacity: 75 to 100 tons per day.
Ore: Nodules of soft pyrolusite and psilomelane in a gangue of quartz, kaolin, calcite and iron oxides.
Assays: Feed, 30 to 40 per cent. MnO_2; concentrate, 72 to 80 per cent. MnO_2; tailing, 10 per cent. MnO_2, upward.

Summary. Graded crushing in jaw crusher and two roll-trommel circuits to 5-mesh. Mechanical classifier to reject −60-mesh material and de-water the sand, which is dried and sized to −5+10-mesh and −10+100-mesh; −100-mesh to dump storage. Wetherill magnetic separators working the two screened grades separately take out a high-iron product on the first pole, which is rejected; make concentrate on the remaining five poles, and reject tailing.

Crimora mill, Virginia. Fig. 114. *(Bul. 173 USBM 48.)*

Ore: High-grade manganese nodules in residual clay and sand; lean.



a, All material sledged through. *b,* 24 in. wide, 22 ft. long. *c,* 30 in. wide, 22 ft. long.

FIG. 114.—Crimora mill.

Summary. Rough concentration in log washers. Log product crushed to about 2-in. and sized into five grades. Coarsest size hand picked; finer sizes jigged separately.

24. Mercury, Hg

Properties. Metal; silver-white, lustrous, liquid under atmospheric pressures at ordinary temperatures. (See also Table 1.) AT. WGT., 200.6. Not acted upon by dry air at ordinary temperatures. Does not decompose water, but that it is slightly soluble in water at ordinary temperatures without decomposition of the water can be reasoned and has been proven experimentally. Oxidizes when heated in the air and the oxide can be broken down by further heating. Insoluble in hydrochloric and in cold sulphuric acids; dissolves in hot concentrated sulphuric acid and is easily soluble in nitric acid. Ion is of basic character only and may be either mono- or bi-valent. Mercury alloys freely with other metals forming AMALGAMS.

Uses. The drug and chemical trades are the principal consumers. Oxides and fulminates are used in making paints and explosives respectively. Smaller amounts are used in electrical apparatus, gold (amalgamating) mills, scientific instruments (thermometers, barometers, and the like). If the mercury boiler proves practical from a power standpoint, consumption will increase markedly.

Ores. Cinnabar is the only economic mineral. It occurs as veins, disseminations or masses of irregular form, not confined to any special type of rock, although igneous rocks are often found in the vicinity. The common gangue minerals are silica and calcite; pyrite or marcasite is usually, and bitumen often, present.

Production. World production averages about 90,000 flasks (75 lb. each) per year. Of this Italy produces slightly more than 50 per cent., Spain nearly 40 per cent. and the United States between 8 and 10 per cent. The foreign deposits are much higher grade than the domestic, hence competition is overwhelming. The principal domestic mines are in California and Texas.

Price fluctuates widely and rapidly. Average yearly prices per 75-lb. flask at New York in recent years were (*Eng. and Min. Jour.-Pr.*): 1919, $92.15; 1920, $81.12; 1921, $45.46; 1922, $58.95; 1923, $66.70; 1924, $69.76.

Treatment. Ores carrying as low as 0.25 per cent. Hg can be treated by roasting more economically than by concentration followed by roasting. The ore is crushed to a size that will permit oxidation of the cinnabar and vaporization of the metal, ordinarily to 1- or 2-in., dried, and then roasted. At some mines hand sorting precedes crushing. Concentration of ore carrying 0.10 to 0.20 per cent. Hg by gravity methods and flotation has been successful experimentally (*120 P 117; Bul. 222 USBM*) but the domestic deposits are too small to permit large-scale treatment and small-scale treatment is not economical.

25. Molybdenum, Mo

Properties. Metal; silver-white, ductile, malleable, difficultly fusible. Ductility increases above red heat. (See also Table 1.) AT. WGT., 96.0. Unchanged in air at ordinary temperatures, but oxidizes on heating. Not attacked by dilute acids, but is attacked by concentrated sulphuric and nitric acids. Ion enters into combination both as a base and as an acid, is tri-, quadri- and sexa-valent, and the compounds in which the valence is highest are the most stable. Alloys with other metals.

Uses. The principal use is in alloy steels containing from 0.15 to 0.5 per cent. Mo in automobile manufacture. Steels containing up to 3 per cent. Mo, usually containing also one or more of the following: chromium, nickel, cobalt, manganese, tungsten or vanadium, are used for permanent magnets, high-speed tools, stainless steels, etc. Molybdenum is also used as a substitute for platinum in jewelry, dental work and gas-engine ignition. Molybdenum chemicals are used in dyeing, ceramics, and fire-proofing textiles.

Ores. The economic minerals are molybdenite, wulfenite, and molybdite. They occur as irregular masses or disseminations in crystalline rocks, fre-

quently associated with bismuth and tungsten minerals, pyrite, pyrrhotite and magnetite. Ores containing from 0.5 per cent. molybdenum upward may be of commercial grade.

Production. World production since 1918 has fluctuated from a high point of 875 tons in that year through a low of 5.5 tons in 1921 to 230 tons in 1924 (*33 MI 500*). The United States produced more than 60 per cent. of the total in 1924, the balance coming from Norway, Canada and Australia. The United States is the principal consumer. High-grade deposits are small and erratic. The principal domestic deposits are in Arizona, Nevada, California, Colorado, New Mexico, Montana and Washington.

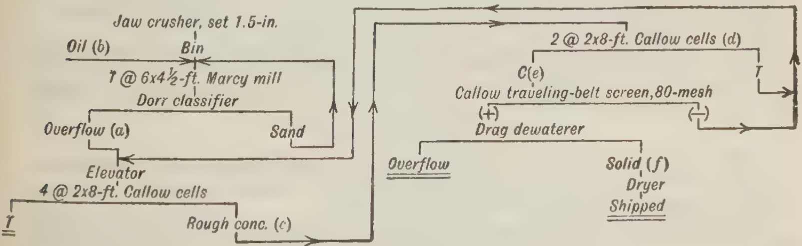
Selling. Concentrate is sold either on the short-ton unit or the percentage basis, reckoned on Mo, MoS_2 or MoO_3. Molybdenite concentrate should contain more than 65 per cent. MoS_2, but concentrate containing 65 per cent. MoS_2 and 25 per cent. pyrite can be successfully converted into ferro-molybdenum (*Spurr and Wormser*). The usual demand is a minimum of 85 per cent. MoS_2 and frequently for 90 to 95 per cent. Arsenic, antimony, barium, bismuth (0.5 per cent.), calcium, copper (0.2 to 0.5 per cent.), phosphorus and tin (0.5 per cent.) are objectionable. PRICES per pound of MoS_2 in 85 per cent. concentrate substantially free from arsenic, bismuth, copper and tin ranged from about $0.40 in 1919 to $0.85 in 1924. Potential production is in excess of present or prospective demand.

Treatment. Wulfenite ores concentrate readily by gravity methods. Molybdenite does not respond to gravity concentration on account of its flaky character and resistance to wetting. Present successful methods of recovery employ flotation. In the past hand sorting, electrostatic separation, air jigging, skin flotation and Elmore vacuum flotation have been used, but none of the plants were highly successful.

Dominion Molybdenite Co. Fig. 115. (*109 J 840.*)

Location: Quyon, Que., Canada.
Ore: Molybdenite and pyrite in quartz diorite. Dissemination, coarse to very fine flakes.
Capacity: 150 tons per 24 hr.
Assays, per cent. MoS_2: Feed, 0.7; concentrate, 90; tailing, trace.
Recovery: 98 per cent.
Ratio of concentration: 125 : 1.

Summary. Flotation (rougher-cleaner routing) with sizing of clean concentrate and rejection of fines. CRUSHING: Jaw crusher and 1-stage ball milling to 40-mesh.



a, −40-mesh. *b*, 0.5 lb. pine oil (G. N. S. No. 5) and 1 lb. kerosene per ton. *c*, 10 to 15 per cent. MoS_2 and about the same in FeS_2. *d*, Sides raised to prevent overflow. Bubble column carried 14 to 18 in. deep. Overflow through 1-in. slot across end. *e*, 60 to 70 per cent. MoS_2. *f*, 85 to 95 per cent. MoS, 2 to 3 per cent. FeS_2.

FIG. 115.—Dominion Molybdenite Co.

It is interesting to compare the relatively coarse flotation feed at this plant with the fine feed (120-mesh) at AMERICAN METAL Co., treating an ore containing granular molybdenite. At the latter plant a somewhat similar flotation operation and 3 or 4 successive cleanings make 65 to 70 per cent. concentrate (MoS_2) and only 82 per cent. sulphide recovery (*61 A 171*). Coghill and Bonardi (*109 J 1210*) working on PRIMOS CHEMICAL Co. ore found that fine grinding flake molybdenum greatly increased tailing loss, and in light of their work the Primos flow-sheet was changed so that 35- or 40-mesh feed was sent to the rougher-flotation machines and the sandy part of the tailing from these was re-ground and re-treated. By this change and a change in oils the tailing was lowered from 0.2 or 0.25 per cent. Mo to 0.12 per cent.

Boykin and Hereford wulfenite mill. Fig. 116. (*Bul. 111, USBM.*)

Location: Mammoth, Ariz.
Ore: Cyanide-plant tailing.
Capacity: 200 tons per day.
Assays: Feed, 1 to 2 per cent. wulfenite; concentrate, 22.6 per cent. MoO_3, 61.8 per cent. PbO.
Ratio of concentration: 100 : 1.

Summary. Gravity concentration by classification and tabling of −4-mesh feed.

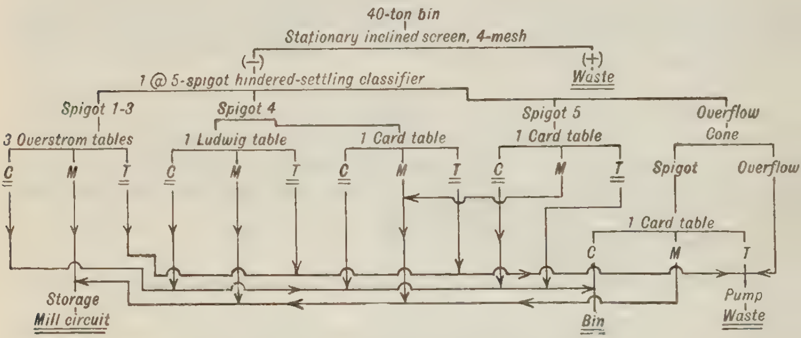


FIG. 116.—Boykin and Hereford wulfenite mill.

26. Monazite

Properties. Monazite is a phosphate of the cerium metals, (Ce, La, Di) PO_4, but is commercially valuable for the content of thoria (ThO_2) which is frequently present in an amount between 5 and 10 per cent. COLOR is red-brown to yellow-brown, greenish or grayish; LUSTER, resinous; HARDNESS, 5 to 5.5; SP. GR., about 5.

Uses. The important use is in the manufacture of thorium nitrate for gas mantles, which are 99 per cent. thoria. Thorium metal is alloyed with tungsten for electric-light filaments. Cerium compounds have a limited use in making a sparking alloy, flaming-arc electrodes, ceramics, dyeing, tanning, etc. Mesothorium, of which minute amounts are obtainable from monazite, is used as a substitute for radium.

Ores are placer deposits in which monazite sand occurs with other heavy minerals such as zircon, rutile, garnet, ilmenite, magnetite, tourmaline and also, of course, with quartz, feldspars and mica.

Production. The principal producing countries are India and Brazil. World production is from 1500 to 3000 tons annually. The principal domestic deposits are in North and South Carolina.

Selling. Concentrate should contain 90 to 95 per cent. monazite and 6 to 9 per cent. ThO_2. PRICE of the Indian mineral was from \$12 to \$15 per unit of thoria in 1924. In the spring of 1926 the quotation (*Eng. and Min. Jour.*-

Pr.) was \$120 per ton for sand containing 6 per cent. ThO_2. Demand is small and potential production in excess.

Treatment consists in rough concentration to reject the lighter sands, followed by careful separation of the heavier sands by gravity concentration, or electrostatic or electromagnetic methods. Sluice concentrate contains 20 to 60 per cent. monazite. When this is dried and closely sized (20-, 50-, 80- and 100-mesh) and treated carefully and by a low-intensity, then a Wetherill high-intensity separator, the products are: low-intensity magnet, magnetite; high intensity; first pole, ilmenite, hematite; second pole, garnet, platinum, epidote, apatite, olivine, tourmaline; third pole, monazite with small amounts of zircon, rutile, epidote, etc.; fourth pole, fine grains of monazite; non-magnetic, gold, zircon, rutile, quartz, feldspar, etc. The gold, zircon and rutile can be separated from the tailing by shaking tables (*TP 110, USBM*; see also *Ladoo*).

27. Nickel, Ni

Properties. Metal; white, lustrous, hard, tenacious, magnetic. (See also Table 1.) AT. WGT., 58.7. Not acted upon by air or water. Attacked with difficulty by hydrochloric and sulphuric acids but readily by nitric acid, forming the corresponding salts in which nickel is a bi-valent base. Tri-valent nickel compounds are unstable and little known. Nickel also forms complex ions, especially with nitrogen compounds as $K_2Ni(CN)_4 \cdot H_2O$. It alloys freely with other metals.

Uses. The principal use is as nickel steel, which is particularly strong, tough and easily machined. Its principal use in the past was for armor plate and projectiles. At present the automotive and steam-engineering industries take large amounts. Nickel is largely used for plating other metals where corrosion is to be resisted. A new important use is in PERMALLOY, used in the manufacture of ocean cable for high-speed transmission.

Ores. The economic minerals are niccolite, millerite, nickeliferous pyrrhotite, pentlandite, garnierite. The two most important deposits of the world are at Sudbury, Ontario, Canada, and on the island of New Caledonia. At Sudbury the ore consists of enormous masses of nickeliferous pyrrhotite segregated at the bottom of a quartz-diorite intrusion, and as scattered, irregular masses in the diorite. The ore contains 1 to 6 per cent. nickel and 1 to 2 per cent. copper. The ore in New Caledonia is garnierite. No nickel mines are worked in the United States, although some few hundred tons of the metal are produced annually as a by-product in the smelting of other ores.

Production. The peak production was 52,000 tons in 1918. In 1922 it was 10,000 tons and in 1924, 38,000 tons (*33 MI 506*).

Price in the spring of 1926 was \$0.35 per lb. for ingot metal (about 98.5 per cent. Ni) to \$0.39 for electrolytic (99.75 per cent. Ni). There is no competition and potential production is greatly in excess of demand.

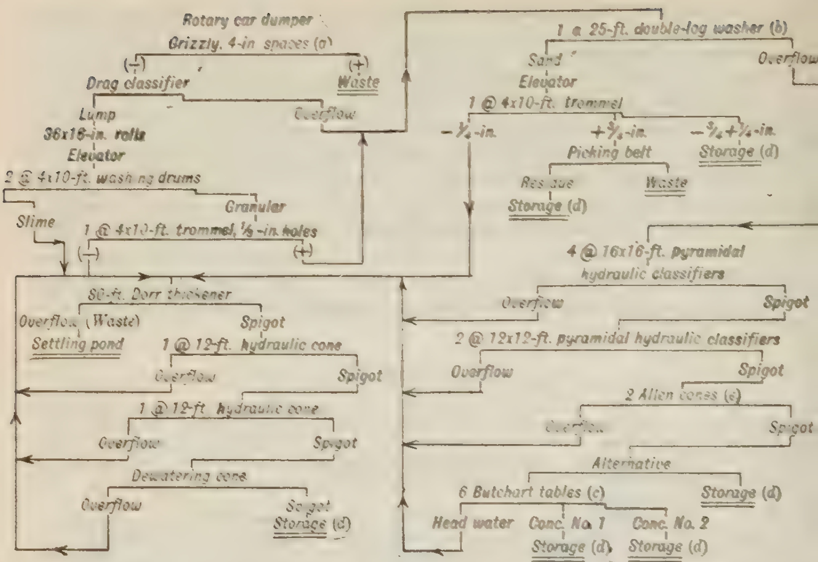
Treatment. Both the Canadian and New Caledonian ores are smelted directly.

28. Phosphate

Properties. Phosphate rock is an amorphous material, principally BONE PHOSPHATE, of the approximate composition $Ca_3P_2O_8$. HARDNESS ranges from 2 to 5. SPECIFIC GRAVITY is from 2.5 to 2.8.

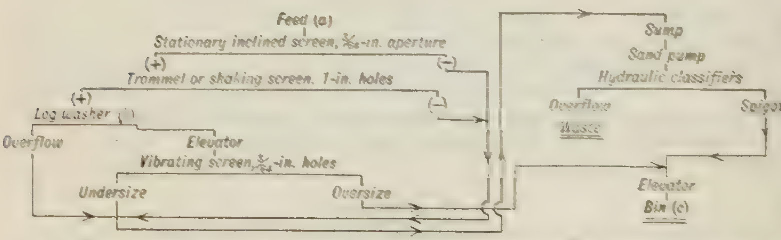
Uses. The principal use is as the raw material for acid-phosphate, super-phosphate and soluble phosphate to form a base for mixed fertilizers. Small quantities are used as a source of phosphorus and in making ferro-phosphorus.

Ores. The principal occurrences are of three types, *viz.:* (1) pebble deposits, in which rounded particles of the phosphate, usually less than 1 in. in size, occur mixed with fine quartz sand and clay in irregular beds under a



a. Organic waste picked. Other material sledged or washed through. *b.* Usually 20 to 30 ft. long, 1 to $1\frac{3}{4}$ in. per ft. slope. *c.* Such separation as is effected depends on the fact that the quartz is smaller than the phosphate and therefore rides higher on the table. *d.* Dried, usually in rotary driers, fed at the cold end, coal- or oil-fired. Usually 4 or 5 by 30 to 50 ft. Capacity, about 100 tons sand or 120 tons rock per 10 hr. from 7 or 8 to 1 or 3 per cent. moisture. Coal consumption, 5 to 6 tons per 10 hr.; power, 5 hp., one man to two driers ([illegible]). *e.* Dorr bowl thickeners have replaced these cones in some washers and saved more fine phosphate.

FIG. 117.—Charleston Mining and Manufacturing Co., phosphate washer (115 J 225).



a. Delivered by centrifugal pump in a pulp containing about 10 per cent. solids. Contains 35 to 50 per cent. −3/64-in., assaying upwards of 68 per cent. B. P. L. and the balance about 35 per cent. B. P. L. *b.* Usually 2-log, 20 to 30 ft. long, 1 to $1\frac{1}{2}$ in. per ft. slope. *c.* See note (*d*), Fig. 117.

Usual capacity, 1500 to 2000 tons per 10 hr. Recovery is usually not over [illegible] per cent. of the phosphate content of the feed.

FIG. 118.—Typical Florida pebble-phosphate washer.

few feet of soil; (2) hard-rock deposits in which the phosphate rock is either in place or in the form of boulders and nodules, in either case mixed with and overlain by residual clays, sand and soil; (3) bedded deposits, *i.e.*, beds of phosphate rock interstratified with sedimentary rocks.

Production. World production was 4,100,000 metric tons in 1919, 7,700,000 in 1924 and in the intervening years ranged between these two extremes. The United States and Tunis together produced about 75 per cent. of this total, each producing about the same amount. Algeria, Morocco, Nauru Island and Ocean Island were the other big producers. The Pacific island deposits are exceptionally high grade (80 to 85 per cent. bone phosphate, B. P. L.). The domestic production comes principally from Florida and Tennessee. The bedded deposits of the western states, Utah, Idaho, Wyoming, and Montana, are enormous (estimated at 6,000,000,000 tons) and readily mined, but cannot compete with the eastern product on account of freight.

Selling. The acid-phosphate market requires a phosphate content (B. P. L. = tri-calcium phosphate) between 70 and 80 per cent. with a maximum of 4.0 to 6.5 per cent. combined $Al_2O_3 + Fe_2O_3$. A usual procedure is to credit 2 per cent. B. P. L. for each per cent. of combined iron oxide plus alumina below an agreed maximum and penalize similarly for excess. Moisture content is usually below 3 per cent. PRICES for domestic consumption, f.o.b. mines, quoted in the spring of 1926 were: Florida, pebble; 76 @ 77 per cent. B. P. L., $5.75 per long ton; 75 per cent., $5; 74 @ 75 per cent., $4.75; 70 per cent. $3.25. Tennessee, rock; lump ($-\frac{3}{4}$-in. screen), base 75 per cent. B. P. L., $6; ground, 95 per cent. −200-mesh, base 65 per cent. B. P. L., $7.25; 70 per cent. base, $8.25 (*J, Mar. 6, 1926*).

Treatment consists in washing in log washers and screen washers. Flowsheets vary somewhat according to whether the ore is pebble phosphate or rock phosphate. See Figs. 117 and 118.

29. Platinum, Pt

Properties. Metal; gray-white, heavy, tough, malleable, ductile, capable of welding at red heat. (See also Table 1.) AT. WGT., 195.2. Not acted upon by air or water, nor appreciably by pure acids. Dissolves rather slowly in AQUA REGIA. Also attacked by fused caustic potash or soda and by phosphorus at red heat. Forms easily-fusible alloys with readily reducible metals. Finely divided platinum occludes enormous quantities of oxygen and hydrogen and exhibits marked catalytic properties, especially in the acceleration of gas reactions. Platinum acts both as a base- and as an acid-forming element, the basic ion having a valence of either two or four.

Uses. Catalytic agent in contact-process sulphuric-acid plants; in jewelry and dental supplies; in scientific apparatus; in incandescent electric-light bulbs. It is being replaced in dental supplies by other alloys and in incandescent lights by alloys possessing the same coefficient of expansion with heat as glass.

Ores. The economic mineral is metallic platinum, usually alloyed with one or more of the elements iron, iridium, rhodium, palladium, osmium and ruthenium. It has usually been recovered from placer deposits near areas of basic igneous rocks; peridotites, pyroxenites, dunites and serpentine. Gravels that carry platinum are usually rich in chromite and olivine. Recently what appears to be a large primary deposit has been found in dunite in South Africa.

Production. World production in 1912 was about 280,000 troy ounces of which 250,000 came from Russia. In 1921, with Russia practically eliminated (5500 oz.) world production dropped to a minimum of 48,000 oz. In 1924 it was 104,500 oz., of which Colombia produced 51,300 oz.; Russia, 40,000;

Canada, 9200; United States, 3500, and Australia, 500. Of the domestic production only 315 oz. was crude mine platinum; of this, 285 oz. was a by-product of California gold dredges.

Prices. The restricted supply has caused an increase in price to an average of $119.09 per troy oz. in 1925. The price in 1908 was $16.32; in 1913, $44.88, and in 1919, $114.61. For a discussion of the South African discovery and the possible effect on prices see *33 MI 583*.

Treatment. Platinum is recovered from gravels in sluices, gold tables and the like (or by pan, batea, rocker, etc., in the case of rich placers) in the same way as placer gold is recovered (see p. 120). It does not amalgamate readily. The platinum that is recovered from gold dredges is caught with black sand and amalgam in the sluices, the amalgam is separated, the residue ground fine and then concentrated in a long tom or rocker until the bulk is small. The final clean-up is made dry by careful and repeated blowing and treatment with a hand magnet.

In refining, the platinum metals are separated. These sell at prices ranging from about $50 per oz. for ruthenium (1924) to as high as $400 per oz. for iridium (1925).

30. Tin, Sn

Properties. Metal; white, lustrous, crystalline, malleable, very ductile at ordinary temperatures; when exposed for a considerable time to low temperatures, the ordinary form changes into a grayish powder of sp. gr. 5.8, known as gray tin. (See also Table 1.) AT. WGT., 118.7. Not acted upon by air or water at ordinary temperatures. When heated in air above the melting point it oxidizes to stannic oxide. At red heat tin decomposes steam with evolution of hydrogen. Tin is attacked by the common mineral acids, both dilute and concentrated, also by strongly basic hydroxides. The ion is both bi- and quadrivalent and acts to form both bases and acids. Tin alloys freely with other metals.

Uses. On account of its resistance to corrosion by air, water and weak acids, tin surfaces are widely used where such corrosive action is to be resisted. Hence tin-plate, which is sheet iron covered with a thin layer of tin, is used for roofs, kitchen utensils and containers for canned goods. Cooking utensils made of copper are tinned to prevent the formation of poisonous copper salts. Important alloys of tin are: soft solder, an alloy of tin and lead which has a lower melting point than either the tin or lead; bronze, bell metal and speculum metal, principally copper and tin; Britannia metal, consisting of tin and antimony, with sometimes copper and zinc; bearing metal and pewter. Lead-tin alloys are used for foil, collapsible tubes and the like. Tin salts are used to weight silks.

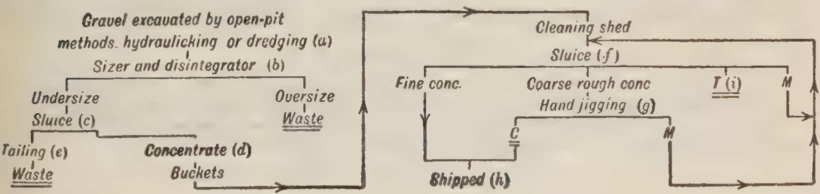
Ores. The principal economic mineral is cassiterite. Stannite is relatively rare. The largest production comes from cassiterite gravels, but primary ores in which cassiterite and sulphides occur in pegmatitic veins are also important.

Production. World production amounts to from 120,000 to 130,000 long tons per year. Of this the placer deposits of the Federated Malay states and of the Dutch East Indies (Banka and Billiton) produce about 50 per cent. and vein deposits in Bolivia 20 to 25 per cent. Other important producers are Australia, China, Nigeria and Siam and, of less importance, Great Britain, Congo, Czecho-Slovakia, India, Unfederated Malay States, and Union of South Africa.

Selling. Tin concentrate should contain 50 to 70 per cent. Sn. Placer-tin concentrate is usually relatively pure. Bolivian concentrate contains impurities such as lead, arsenic, bismuth, antimony, copper, iron and sulphur that are difficult to eliminate and hence highly objectionable. Average yearly PRICES of metallic tin (99 per cent. Sn) at New York were: 44.25 cents per lb. in 1913; 63.33 in 1919; 48.27 in 1920; 28.58 in 1921; 31.83 in 1922; 41.80 in 1923; 49.67 in 1924; and 56.79 in 1925 (*121 J 145*).

Treatment. Cassiterite placers are mined and treated by the usual placer methods. The Bolivian vein deposits are of several different varieties and degrees of complexity. The tin mineral is invariably cassiterite. In the simple oxidized ores the accompanying minerals are principally quartz, feldspars and iron oxides, and separation is simple. The sulphide ores, frequently occurring in the same mines below the oxidized ores, contain, in addition to cassiterite and the gangue minerals, part or all of the following: pyrite, chalcopyrite, bornite, arsenopyrite, wolframite, bismuth minerals, silver minerals, galena, and sphalerite. Many of these ores are of high grade and the cassiterite occurs in relatively coarse particles, but the complexity of the ores makes concentration difficult and the inaccessibility of the district makes changes in methods slow to be effected. In Cornwall the ores are low grade, more or less complex and the cassiterite is very finely dispersed. Many of the mills are ancient, as mills go, owners and operators are highly conservative, and most of the flow-sheets, judged from the viewpoint of American operators, are antiquated.

Placer tin (Fig. 119). The ores (gravels) are typically low-grade, representing tailing from previous placer operations on higher-grade gravels or low-grade ground that was passed over in the earlier work. In the typical flow-sheet coarse material is removed on a screen, a relatively large amount of low-grade concentrate is made in sluices and this concentrate is cleaned up by hand on small film-sizing tables and hand jigs.



a, See *Peele*, Sec. 10, Placer Mining Methods. *b*, On dredges a revolving stone screen with 0.5- to 0.75-in. round holes is ordinarily used here; in hydraulic mining a sluice grizzly and in open-pit mining a disintegrator somewhat resembling a log washer or one consisting of a horizontal pan in which the material is harrowed by stakes depending from revolving radial arms. *c*, 4 to 6 ft. wide, 60 to 300 ft. long; grade, 1 in 24 to 1 in 40, depending upon percentage of moisture in feed pulp. No riffles, but 3 × 2-in. stops are placed across the bottom at 6- to 10-ft. intervals, and as concentrate builds up behind these the height is increased to 9 or 12 in. *d*, Collected at intervals of several hours to a week (depending upon rate of accumulation) by shutting off feed, turning in a small stream of clear water, and shoveling over carefully. (See Sec. 8, Art. 11.) The crude concentrate finally collected contains from 10 to 50 per cent. cassiterite, the balance being black sand, ilmenite, pyrite, etc. *e*, Probably contains 10 to 15 per cent. of the tin in the feed. *f*, 10 to 12 ft. long, 9 to 10 in. deep, converging from 3 or 5 ft. at the head end to about 15 in. at the discharge end. Water supplied full width at the head end over a weir board 6 to 7 in. high. Operated first with a fairly strong stream of water and hoeing of the material to remove the bulk of the sand tailing. The residue is then washed with a weak stream and the coarse material collected at the lower end. The remainder is finally washed again with a heavier stream and at the same time brushed up-slope, yielding fine concentrate and middling. *g*, Tin-plate sieve, 12 in. diam., 3 in. deep, 60- to 80-mesh apertures. *h*, Assays 70 to 76.5 per cent. Sn. *i*, About 0.1 per cent. Sn.

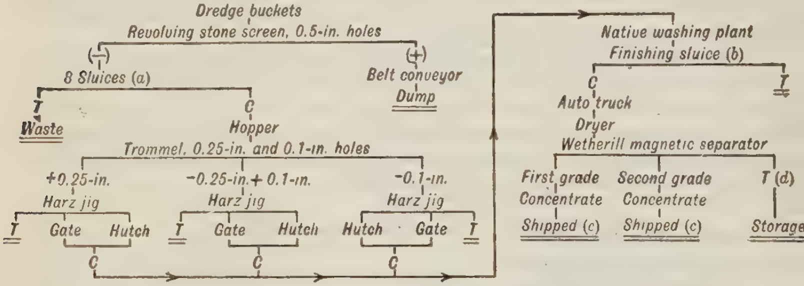
Fig. 119.—Typical Malay placer-tin plant. (*15 MM 327*; *34 IMM 357*).

Summary. No crushing. Concentration by 2-stage sluicing and hand jigging of coarse finishing-sluice concentrate.

On two of the Malay dredges of the YUKON GOLD CO., screen undersize is sent to a specially designed 4-compartment hydraulic spitzkasten, 6 × 18 ft. with a strong horizontal stream of hydraulic water flowing under the main pulp stream. Overflow goes to waste and the spigot products are fed into four 4-compartment Harz jigs (36 × 48-in. sieves) bedded with 0.5-in. lumps of tin or iron ore and making hutch concentrate. Products of the first two hutches of the three coarse jigs are sent to a native cleaning shed and sluiced as described above; products from third and fourth compartments go to a high-speed jig that treats the fourth-spigot product of the classifier and makes finished concentrate and tailing. Recovery of 97 to 98 per cent. of the tin in the feed is claimed, but at the expenditure of 30 to 40 hp. additional, as compared to the ordinary sluice, and with the requirement of specially skilled labor and closer supervision.

Portuguese American Tin Co. Fig. 120. *(104 J 1109.)*

Location: Guia, Portugal.
Ore: Placer tin; cassiterite in gravel.
Capacity: 40 to 50 cu. yd. per hr.
Power: 25 hp. for jigs and screens; 85 hp. for pumps.



a, 13 in. wide, 6 in. deep, 80 to 100 ft. long. Transverse iron riffles, 1⅝ in. deep and 2½ in. apart. Six sluices constantly in use while the other two are being cleaned up. *b,* Narrow, deep launder with slight slope and strong water current. Material hoed over and up-stream. *c,* Averages 68 per cent. Sn. *d,* Principally ilmenite.

FIG. 120.—Portuguese American Tin Co.

Simple low-grade tin ores

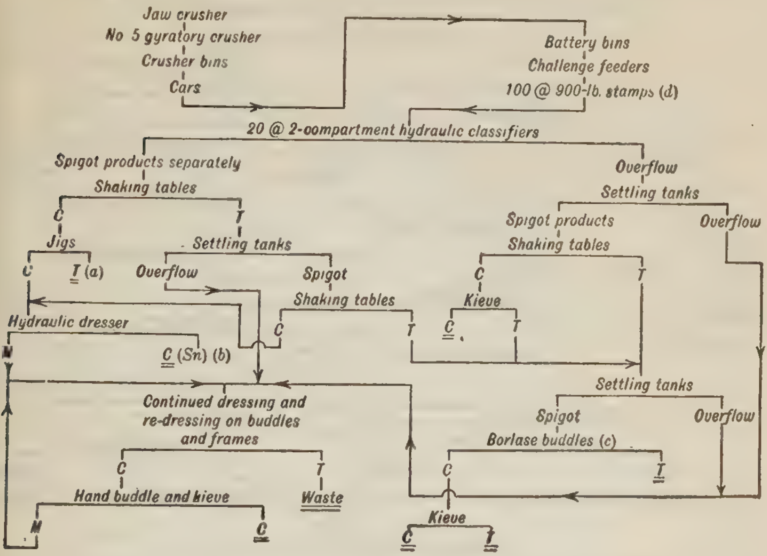
The method of treatment is typified by the flow-sheet of the ANCHOR mine and the primary machines in the EAST POOL mill. It consists in preliminary fine grinding (−0.5-mm.) followed by repeated passage of the tin-bearing pulp over slime-gravity concentrators with re-treatment of the rough concentrate to raise the grade, middling being returned to the circuit. It is a surprising element of these flow-sheets that no re-grinding of tailing is practiced, notwithstanding the usually very fine dissemination of the cassiterite, with the result that substantially no tin not freed in the primary grinding is saved.

Anchor mine. Fig. 121. *(109 P 65.)*

Location: Lottah, Tasmania.
Ore: Low grade. Cassiterite in granite. More than half the cassiterite will pass 200-mesh.
Capacity: About 300 tons per 24 hr.
Assays, per cent. Sn: Feed, 0.10 to 0.16; concentrate, 68 to 73; tailing, 0.025 to 0.03.
Recovery: 70 to 75 per cent.
Ratio of concentration: 550 : 1.

Summary. Gravity concentration by repeated roughing of roughly classified products with cleaning and re-cleaning of concentrate and re-treatment of middling without re-grinding.

This is an exceptionally low-grade ore and the repeated re-treatment could only be justified economically with a valuable metal. As it is, the lower limit of tin assay in the feed (0.10 per cent.) is just about the lower economic limit.



a, Topaz, heavy sand, iron, etc. *b,* 73 per cent. Sn. All other concentrate worked up to 68 to 70 per cent. *c,* Building type. *d,* 0.054-in. Ton-cap.

Fig. 121.—Anchor mine.

Complex tin ores

There are four types, *viz.:* (1) Bolivian sulphide ores, low in lead and silver and containing no other minerals of economic value (see Avicaya mill and Compañia Estañifera de Llallagua); (2) the same, but high in silver and usually containing economic amounts of gold, lead and copper (Socavon de Oruro); (3) Cornish ores, carrying wolfram and arsenic in economic quantities in addition to tin (East Pool); and (4) ores containing tin, lead and wolfram in economic quantities (Butler mine). The summaries of the following flow-sheets set forth the typical features.

Avicaya mill. Fig. 122. *(114 P 774; 115 P 343.)*

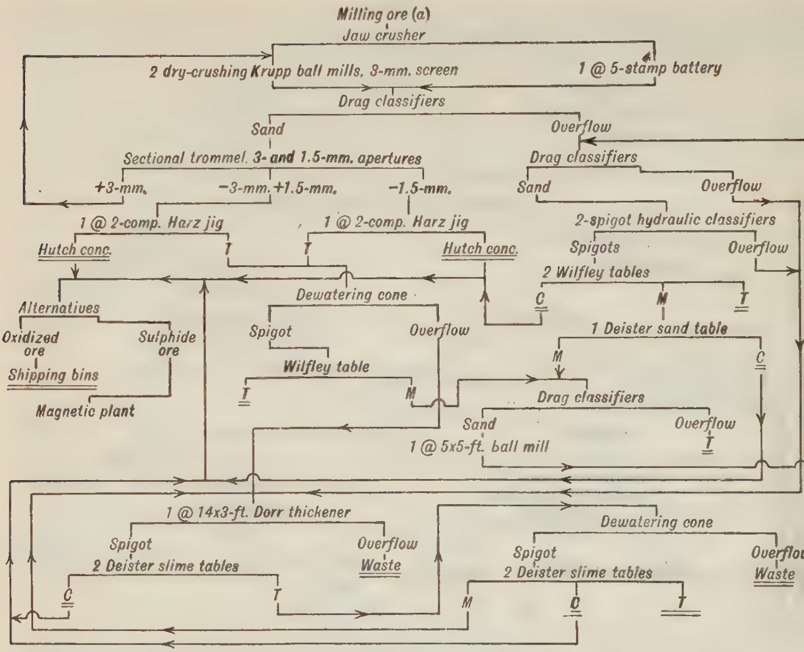
Location: Pazna district, Bolivia.

Ore: Oxidized: cassiterite in a silicious gangue with some iron oxides. Sulphide ore: cassiterite and pyrite in quartz with minor amounts of chalcopyrite and other sulphides and some feldspar and tourmaline.

Capacity: 50 tons per day.

Assays, per cent. Sn: Feed, 5; concentrate (oxidized ores), 60 to 65; sulphides, 50 to 55; tailing, −1.

Summary. Step gravity concentration beginning at 3-mm. with repeated treatment of fine sand making at each step a concentrate for magnetic treatment and a middling for re-grinding or re-concentration, according to fineness. Magnetic treatment is unnecessary with oxidized ores.



a, Comprises upwards of 50 per cent. of the mine product, the balance, both waste and lump cassiterite, having been cobbed out on sorting floors.

FIG. 122.—Avicaya mill.

Compañia Estañifera de Llallagua, magnetic plant. Fig. 123. *(100 J 513.)*

Location: Llallagua, Bolivia.

Ore: Cassiterite-arsenical pyrite concentrate from gravity-concentration mill. (For type of gravity-concentration mill, see above.)

Capacity: 10 tons per 24 hr.

Assays:

	Sn, per cent.	Fe, per cent.	S, per cent.
Feed	31.80	24.56	25.00
Concentrate (Table 87)	68.05	2.90	2.09
Tailing	3.0	....	....

Recovery: 93 to 95 per cent.

Ratio of concentration: about 2 : 1.

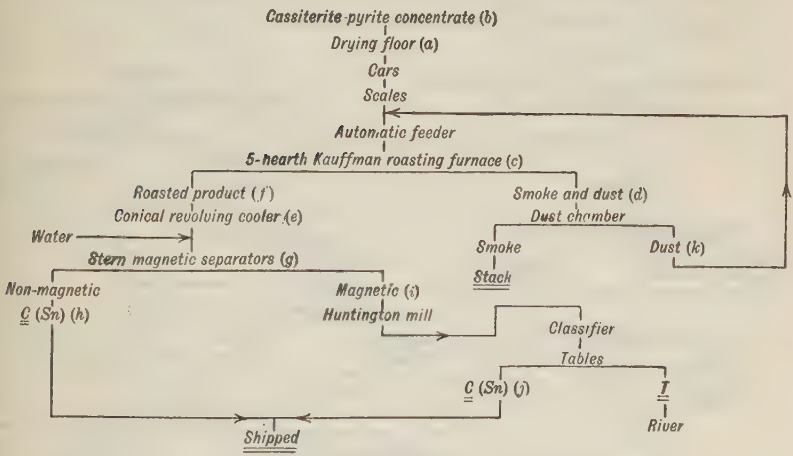
Cost (3 mo., 1914) per ton milled was $1.94 to $2.65.

Summary. Roasting to render pyrite magnetic, followed by magnetic separation of iron- from tin-bearing minerals.

At some plants the iron is "flash-roasted" only.

Table 87. Analysis of Llallagua tin concentrate. (*After Copeland and Hollister*)

Material	Per cent.
Tin oxide (68.32 per cent. Sn)	86.670
Fe	4.746
Ni	0.023
Cu	0.060
Bi	0.360
Pb	0.070
Zn	0.225
Ag	0.006
TiO_2	0.400
WO_3	0.560
CaO	0.130
SiO_2	2.240
S	3.586
O and loss	0.924
	100.00



a, Concrete floor on which material is hand raked until it contains about 5 per cent. moisture. *b,* Mostly smaller than 1-mm. *c,* Similar to McDougall furnace. Roasted until sulphur content is lowered from 25 or 27 per cent. to 10 or 12 per cent. Burning sulphur furnishes necessary heat. Properly roasted material appears black with metallic luster. Reddish, over-roasted material causes poor work on the magnetic separators and too much iron in concentrate. *d,* Less than 5 per cent. of furnace feed. *e,* Similar to short conical trommel, but with un-perforated jacket. Serves also to equalize feed rate to separators. *f,* Assay: 33.3 per cent. Sn, 12.76 per cent. S, 29.3 per cent. Fe. *g,* Draws about 6 amp. at 110 volts. 14 r.p.m. About 18 gal. per min. required to feed and remove concentrate from one separator. *h,* Assay, 68.05 per cent. Sn. Separator recovery = 93 to 95 per cent., equivalent to +90 per cent. of tin entering furnace. *i,* Assay: 3.8 per cent. Sn, 21.22 per cent. S, 50.07 per cent. Fe. *j,* Table recovery about 70 per cent., equivalent to 3.5 to 5 per cent. of tin entering furnace. *k,* Rarely over 5 per cent. Sn.

FIG. 123.—Compañia Estañifera de Llallagua, magnetic plant.

Socavon de Oruro. Fig. 124. (*6 MM 301.*)

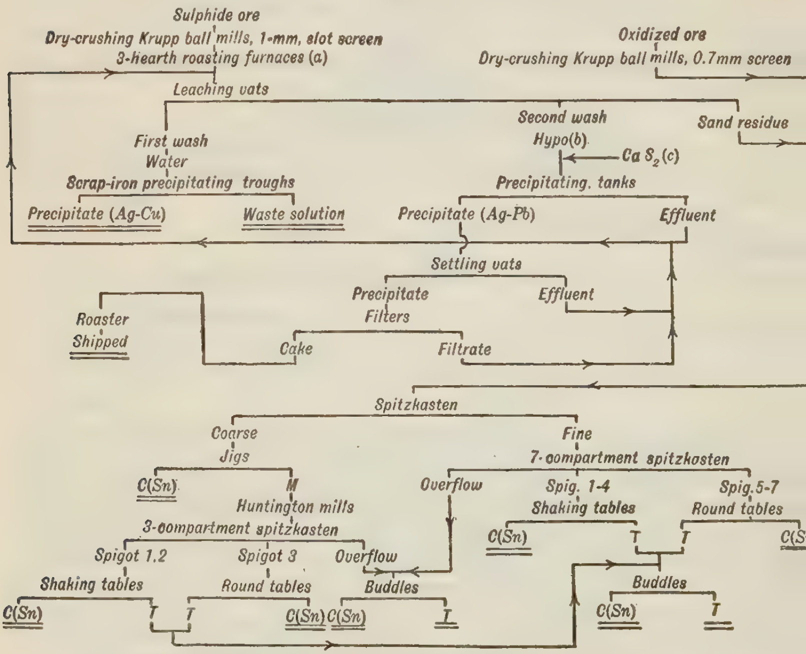
Location: Machacamarca, Bolivia.

Ore: Complex sulphide and oxide ores containing tin, silver, gold, lead, copper, iron, antimony and arsenic in a silicious gangue.

Assays:

	Ag, oz.	Au, oz.	Sn, per cent.	Pb, per cent.	Cu, per cent.
Feed	39	....	3–10	....	....
Ag-Cu precipitate	250	....	....	....	50
Ag-Pb precipitate	35	4	....	23	2
Concentrate (Sn):					
Jig and sand table	....	....	+60	....	....
Slime table	....	....	30–60	....	....
Buddle	....	....	−30	....	....

Summary. Two-stage leaching to recover silver, gold, copper and lead followed by gravity concentration of leaching-plant tailing. Crushing: The notable feature is dry-crushing in screen-discharge ball mills. This is typical of what is probably the best practice in relatively fine granulation for roasting. The Huntington mills would be replaced in more modern practice by a revolving cylinder mill (rod, ball or tube).



a, Sulphur reduced from 30 to 3 per cent. About 4 per cent. sodium chloride added on last hearth. *b*, 0.5 per cent. sodium hyposulphite. 10 to 12 days. *c*, Made on the ground by boiling together sulphur and lime, both obtained locally.

Fig. 124.—Socavon de Oruro.

East Pool mill. Fig. 125. *(6 MM 115.)*

Location: Cornwall, Wales.
Ore: Complex mixture containing cassiterite, wolframite, arsenopyrite and chalcopyrite in silicious gangue. Cassiterite finely disseminated.
Assays: Feed, 0.5 to 1 per cent. Sn, about the same amount of As_2O_3 and half as much WO_3.
Recovery: 60 to 70 per cent. Sn.

Summary. Gravity concentration to reject rocky tailing; roasting to recover arsenic and render iron magnetic; leaching to remove soluble iron, and two-stage magnetic separation to separate tin and wolfram.

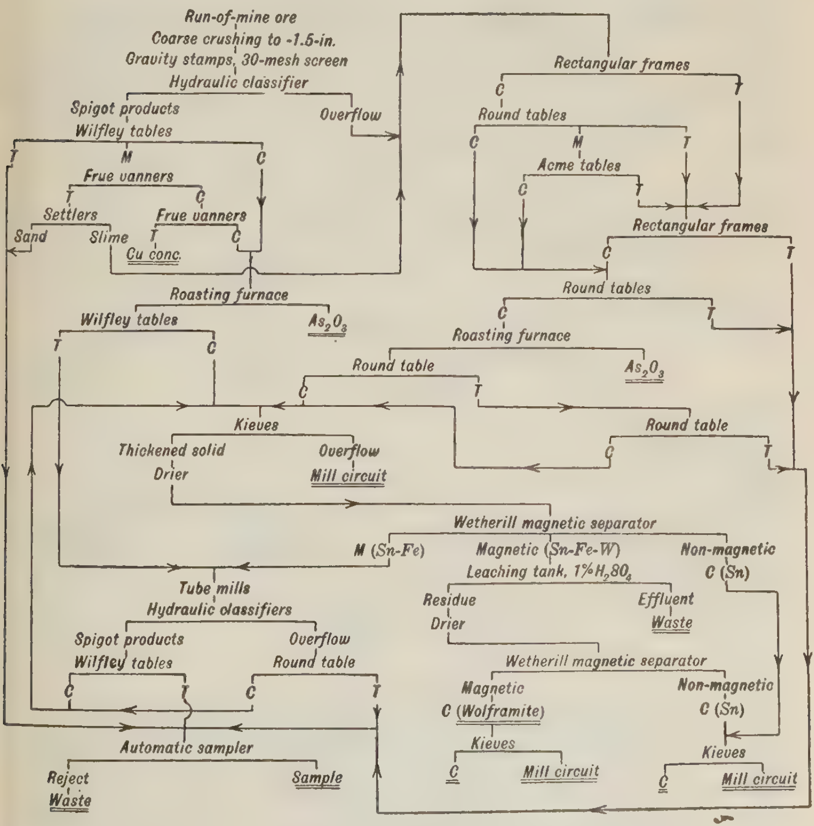


Fig. 125.—East Pool mill.

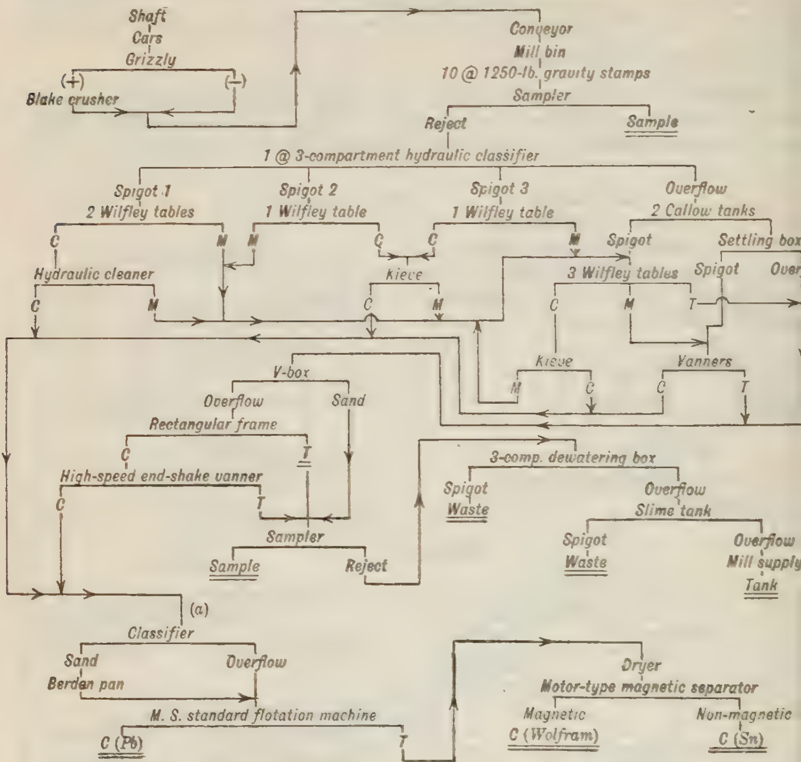
Butler Mine. Fig. 126. *(106 J 530.)*

Location: Torrington, N. S. W.
Ore: Complex tin-wolfram-lead.
Recovery: Sn, 80 per cent.; WO_3, 68 per cent.; Pb, 66 per cent. in gravity mill and 98 per cent. by flotation = 64.5 per cent.

Summary. Collective gravity concentration on tables, vanners and frames with flotation of gravity concentrate to separate lead, and magnetic separation of flotation tailing to separate tin and wolfram.



a, Average, 53 per cent. Sn, 12 per cent. WO_3, 5 per cent. Pb.

Fig. 126.—Butler mine.

31. Titanium, Ti

Properties. Metal: steel gray, lustrous, non-crystalline structure: hard, brittle, non-ductile. (See also Table 1.) At. wgt., 48.1. Oxidizes to TiO_2 when heated in air. Powdered metal reacts slightly with boiling water with evolution of hydrogen. Dissolves in warm hydrochloric and cold dilute sulphuric and nitric acids. In the important compounds the ion is quadri-valent, both base- and acid-forming. Ion is also tri-valent.

Uses. The principal use has been as a de-oxidizer and cleanser in steel making. Titanium-treated steels are said to be stronger and tougher than untreated steels. They are used for axles, tires, and other forgings; gears and pinions, plates, castings and rails. The tonnage of the latter has decreased from over 250,000 in 1910 to 2?,000 in 1916, due to the increasing use of open-hearth over Bessemer steel for rail manufacture and the uncertainty as to the benefit of titanium in open-hearth smelting. At present the demand for ferro-titanium is small in comparison to the supply. Other titanium alloys are those with aluminum and copper. Titanium-aluminum bronze is said to have physical properties equal to phosphor and manganese bronzes and to be lighter. Titanium salts are used in textile and leather industries for dyeing, mordanting and bleaching. There is also a limited

use of titanium compounds in the ceramic, dental and metal-ceramic industries and in the making of arc-lamp electrodes. The use of titanium oxide as a paint pigment is small but increasing.

Ores. The economic minerals are rutile and ilmenite. Ilmenite occurs rather widely associated with magnetite in deposits which, if the smelting problem were solved, would be of commercial importance. These deposits are not of the enormous size popularly believed, but two of them, one in New York and one in Wyoming, are reported by Singewald (*Bul. 64, USBM*) to be of such extent as to be of importance as iron producers. Rutile occurs in igneous, sedimentary and metamorphic rocks as microscopic grains included in the silicate rock-forming minerals; as scattered, separate grains, and as masses. The latter occurrence is the only one of economic importance. Only four deposits of commercial size are known; in the United States, in Virginia; in Quebec, Canada; in Norway; and in southern Australia.

Production of rutile concentrate, 95 per cent. TiO_2, at the Virginia mine ranges from less than 100 to less than 600 tons per annum and ilmenite concentrate (52 per cent. TiO_2) is produced in the same plant in slightly greater quantity. Rutile and ilmenite are also obtained as by-products in the treatment of monazite sand.

Price of high-grade rutile concentrate (94 to 96 per cent. TiO_2) varies from $0.10 to $0.25 per lb. ($0.12 to $0.15 for granular Virginia and $0.17 to $0.30 for −100-mesh in March, 1926). Ilmenite (52 per cent. TiO_2) was quoted (*J. Mar., 1926*) at $0.015 per lb. f.o.b. Virginia points and $60 per short ton, Florida mines.

Treatment at the Virginia mines consists in wet-gravity concentration to collect a mixed rutile-ilmenite concentrate and high-intensity magnetic separation to take out rutile concentrate and leave ilmenite concentrate.

32. Tungsten, W

Properties. Metallic gray, hard, dense, malleable and remarkably tenacious and ductile. It can be drawn into finer wire than any other metal. The fine wire has exceptionally high tensile strength. (See also Table 11, Art. 136.) Not affected by air at ordinary temperatures but burns to the trioxide if heated sufficiently. Not attacked by water or the common acids. Dissolves slowly in alkali hydroxides and in fused alkali nitrates, nitrites and peroxides. It is hexa-valent. The metal alloys readily with nickel, cobalt, molybdenum, chromium, iron, manganese, vanadium, uranium, aluminum and titanium.

Uses. More than 95 per cent. of all tungster mined goes into the manufacture of ferro-alloys and tungsten steels. Tungsten is an essential element of high-speed tool steels which are indispensable in present-day manufacturing. Other uses for the metal are for magnet steel, alloys with aluminum, copper, zinc, nickel, cobalt and other metals, incandescent lamp filaments, electrical apparatus, X-ray tubes, coating for sound reproduction, and as a catalyzer in production of ammonia from atmospheric nitrogen. Tungsten salts are used for fire-proofing cloth, as mordants in dyeing, and for coloring glass and porcelain.

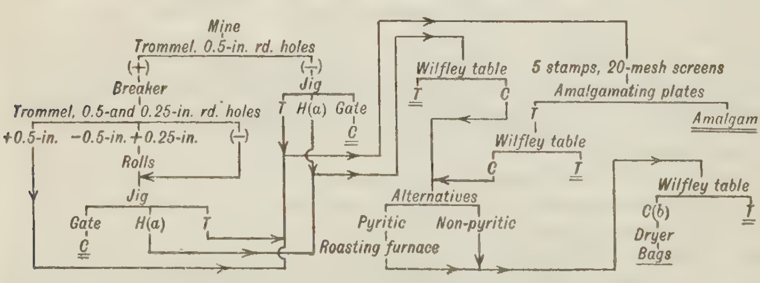
Ores. The economic minerals are scheelite, hübnerite, ferberite and wolframite. Deposits are usually placers or fissure veins, less commonly in pegmatites and contact-metamorphic zones. The usual gangue minerals are quartz, fluorite, cassiterite, tourmaline, mica, etc., occasionally sulphides. The country rock is commonly granite, less frequently quartzite, limestone and metamorphic rocks.

Production. World production of tungsten concentrate (60 per cent. WO_3) in 1914 was 8000 metric tons. The peak production was 32,000 tons in 1918. Production in the years 1921 to 1924 was 5800, 9700, 8000 and 550 tons respectively. Of this 55 to 65 per cent. comes from China and 12 to 15 per cent. from Burma. The United States is a small producer under normal circumstances, although in 1918 United States production was about 4000 tons (*33 MI 721*).

Selling. Tungsten concentrate for making ferro-tungsten should carry upwards of 65 per cent. WO_3 and not more than 0.5 per cent. each of Sn, Cu, P, As and S. Lower grades may be used in chemical manufacture (*Spurr and Wormser*). Sales are usually based on the 20-lb. unit. Prices of concentrate on this basis, in the United States, have ranged from a high of $34 per unit for 60-per cent. concentrate for the year 1916 to a low of $3.20 in 1921. The quotation in March, 1926 (*J*), for wolframite concentrate at New York was $11.50 to $12.50 per unit. Foreign prices are much lower, the American price being artificially maintained by the tariff.

Treatment. There are two general types of mills, designed to treat the two entirely different general classes of ore in which tungsten occurs. The American and some Australian ores consist essentially of the tungsten mineral, usually scheelite or ferberite, in a silicious gangue, while most of the foreign ores that are being worked are complex and carry wolframite with cassiterite and iron and lead sulphides. The simple ores are usually of higher grade than the complex and the tungsten mineral more coarsely disseminated. The Glenorchy flow-sheet is typical of the older practice in treating the simple ores. Variations comprise hand sorting ahead of the jigs, rough classification prior to tabling, and magnetic separation of roasted concentrate. The Tungsten Mines Co. mill is typical of modern practice on low-grade simple ores. Mills treating higher-grade ores usually include jigging and may include hand sorting. This modern practice recognizes the friability of the tungsten minerals and the whole endeavor is to crush so as to produce as little slime as possible and to begin removal of concentrate as soon as the mineral is free. In treating higher-grade ore, tailing from slime tables and vanners is usually run over rag frames and the frame concentrate cleaned or shipped to electric-furnace plants or mixed with the higher-grade coarse concentrate. Recoveries on simple ores range from 65 to 85 per cent., depending on the grade of feed and elaborateness of plant. The S. and M., the Burma Queensland, and the East Pool flow-sheets are illustrative of methods of separating wolframite from complex ores. In all cases the practice is to make a collective gravity concentrate containing the wolfram and to utilize the permeability of wolframite to effect its separation from the non-magnetic portion of the roasted concentrate. When, as is the case at East Pool, the collective concentrate contains iron, magnetic separation of wolframite from the iron is difficult or impossible. At East Pool the difficulty is overcome by leaching out the iron oxide with sulphuric acid.

Glenorchy Scheelite Mine Co. Fig. 127. (*113 P 136.*)



a. 20-mesh. *b.* 70 per cent. WO_3.

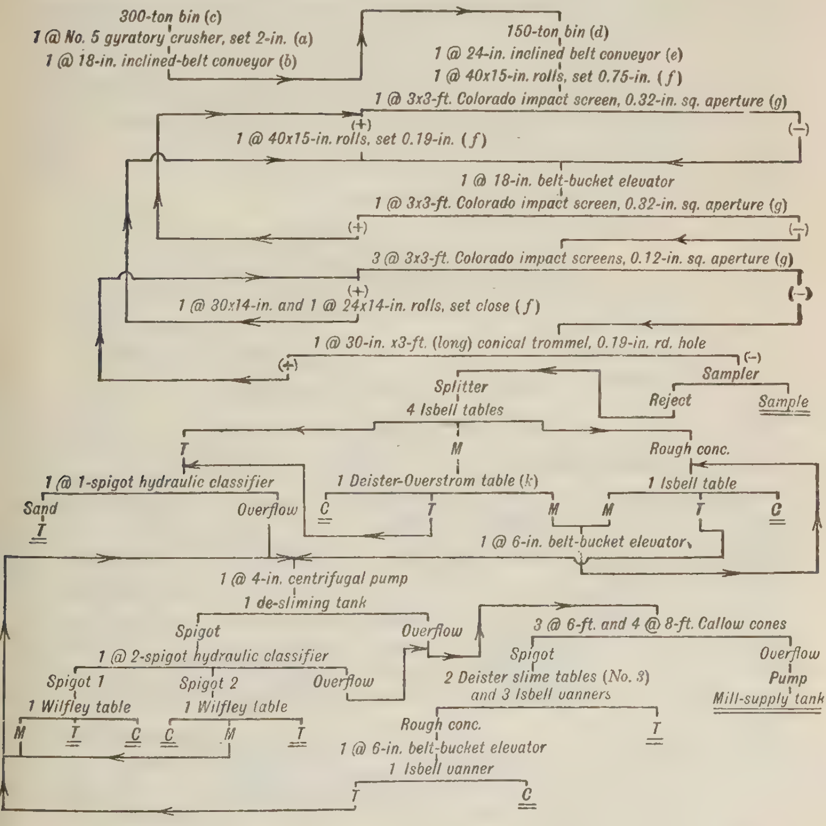
Fig. 127.—Glenorchy Scheelite Mine Co.

Location: Glenorchy, New Zealand.
Ore: Scheelite with pyrite, arsenopyrite and gold in quartz veins in hard, crystalline schist.
Assay: concentrate, 70 per cent. WO_3.
Recovery: 7.1 per cent. of feed as WO_3.
Cost (1907 to 1914 aver.): $1.10 per ton milled.

Summary. Gravity concentration by jigs and tables, beginning at 0.5-in. Harder part of feed and jig middling re-ground to 20-mesh and concentrated (rougher-cleaner routing) on tables. Roasting is practiced to convert pyrite to porous iron oxide and thus lower its effective specific weight and render it separable from the scheelite by gravity (table) concentration.

At another New Zealand mill pyritic scheelite concentrate is given a flash roast only and the now permeable pyrite particles are separated magnetically.

Tungsten Mines Co. Fig. 128. (*Q.*)



a, See Sec. 3, Table 15. *b,* 23 ft. long; slope, +4 in. per ft.; 60 ft. per min; 20-in. head and tail pulleys; 5-ply belt. *c,* Flat-bottom. Live capacity, 100 tons. *d,* Flat-bottom. Live capacity, 70 tons, center-bottom draw. *e,* 19 ft. long, slope, +3.25 in. per ft.; 12 ft. per min.; 20-in. head and tail pulleys; 5-ply belt. *f,* See Sec. 3, Table 22. *g,* See Sec. 5, Table 34. *k,* See Sec. 10, Art. 19.

Fig. 128.—Tungsten Mines Co.

Location: Bishop, Cal.

Ore: Scheelite in a gangue principally (90 per cent.) garnetite with small amounts of epidote, tremolite, calcite, etc.

Capacity: Aver., 240 tons per 24 hr.; max., 350 tons.

Assays, per cent. WO_3: Feed, 0.4; concentrate, 62; tailing, 0.09.

Recovery: 65 to 71 per cent.

Ratio of concentration: 200 : 1.

Labor: 16 tons per man-shift, operating; 60 tons per man-shift on repairs.

Water: 6 to 6.5 tons per ton milled.

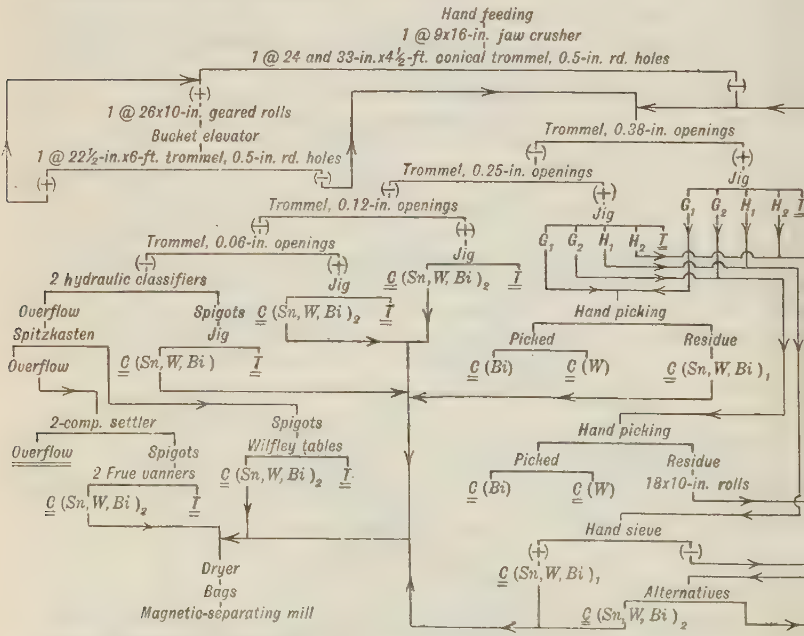
Running time, 70 per cent. of possible: High delay due to repairs caused by abrasive character of ore.

Distances: Mine to mill, 2500 ft., mule tramming; mill to market, 13 miles to railroad, thence to eastern U. S.; water transported 2 miles by open ditch and gravity pipe line; power transmitted 4 miles at 33,000 volts.

General: Slightly sloping mill site.

Summary. Gravity concentration on tables and vanners after careful graded crushing to 0.12-in. CRUSHING: Gyratory from 11- to 2-in.; rolls from 2- to 0.75-in., open circuit; rolls from 0.75- to 0.32-in., closed circuit; rolls from 0.32- to 0.19-in., closed circuit. CONCENTRATION: Roughing unclassified pulp on shaking tables and cleaning rough concentrate and primary middling separately on shaking tables. Primary-table tailing de-slimed, sand rejected, slime joined with primary-cleaner tailing, classified, the sands treated on Wilfley tables and the slimes on Deister slimers and vanners. Slime concentrate cleaned on a vanner.

S. and M. mine. Fig. 129. (*120 P 229.*)



NOTE: Subscripts indicate first- and second-grade concentrate. The principal difference is in the pyrite content, the "firsts" containing but little while the "seconds" contain considerable. Neither contains much gangue.

FIG. 129.—S. and M. mine.

Location: Monia, Tasmania.

Ore: Cassiterite, wolframite, scheelite, bismuthinite, bismutite and pyrite in quartz gangue with some fluorite, mica and topaz. The quartz is very friable and the economic minerals occur in coarse grains and patches so that 0.5-in. crushing frees most of the values.

Capacity: 100 tons per 24 hr.

Assays of concentrate: "Firsts" (see note on flow-sheet)—Sn, 35 per cent.; WO_3, 35 per cent.; Bi, 2.5 per cent. "Seconds"—Sn, 12 per cent; WO_3, 10 per cent.; Bi, 3.5 per cent.

General: Mill 18 miles from railroad. Concentrate shipped to Launceston.

Summary. Gravity concentration by jigs, tables and vanners after careful sizing and classification. Hand sorting and magnetic concentration to separate the collective concentrate thus obtained.

Burma Queensland Corporation. Fig. 130. (*123 P 821.*)

Location: Wolfram, N. Q., Australia.

Ore: Molybdenite, wolframite, metallic bismuth, bismuthinite, bismutite and a little scheelite, in quartz and granite. The economic minerals occur in coarse grains and patches.

Capacity: 110 to 120 tons per 24 hr.

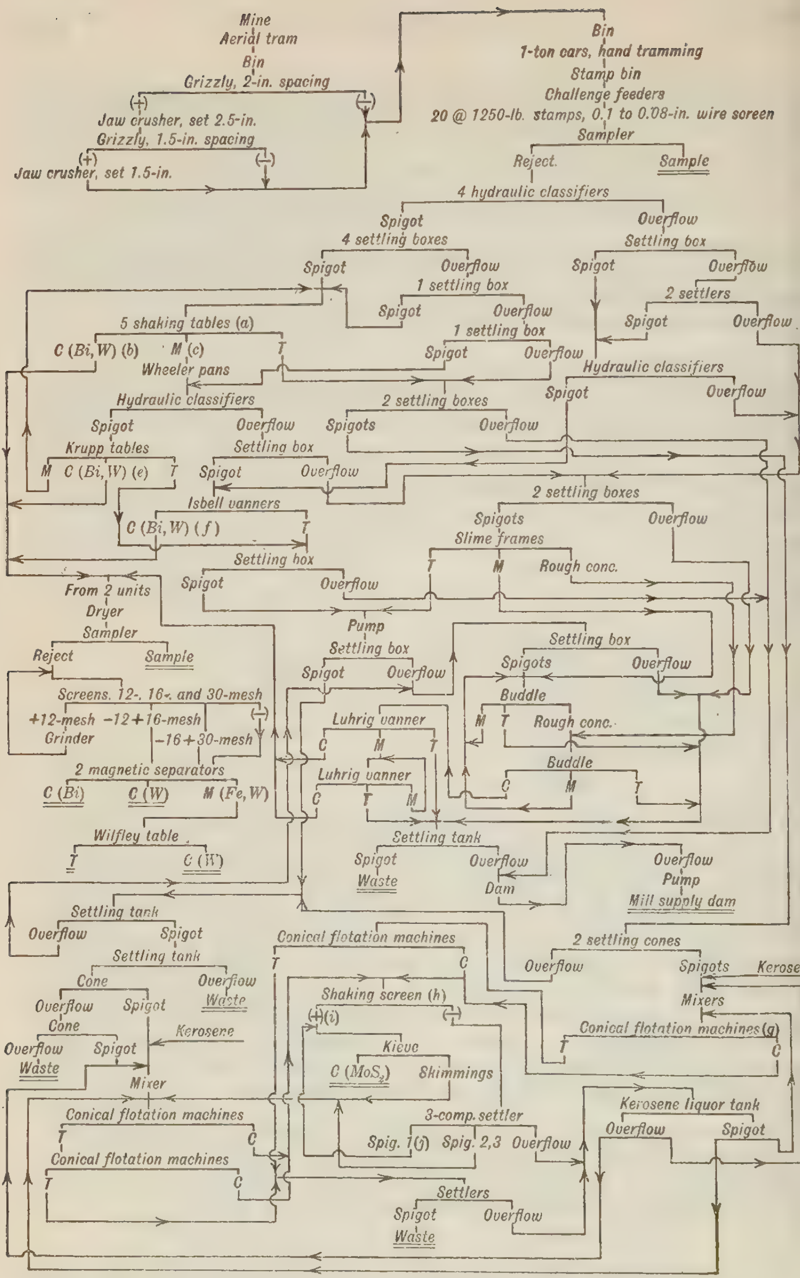
Assays: See Table 88.

Table 88. Assays of intermediate and final products, Burma Queensland Corp.

Reference letter	Product	Assay, per cent.		
		WO_3	Bi	MoS_2
b	Primary-table concentrate	30–45	5–7	....
c	Primary-table middling	8–10	....	5
	Primary-table tailing	0.1–0.13	....	....
e	Secondary-table concentrate	25–40	3–5	....
f	Primary-vanner concentrate	15–25	3–4	....
i	Coarse flotation concentrate	....	....	85–94
j	Fine flotation concentrate	....	....	80–85

Summary. Gravity concentration to make a collective tungsten-bismuth concentrate followed by magnetic concentration to separate tungsten from bismuth. Gravity tailing floated, yielding molybdenum concentrate and final tailing. Crushing: Two-stage reduction in jaw crushers followed by gravity stamps to reduce pulp to 8-mesh. Pans used to re-grind primary-table middling. Plus-12-mesh gravity concentrate ground through 12-mesh for magnetic separation. No other grinding. Concentration starts on 8-mesh pulp, which is classified to an excessive degree in preparation for shaking-table, vanner, frame and buddle treatment. Flotation feed (gravity-concentration tailing) is −8-mesh size. Magnetic-plant feed (gravity concentrate) is −12-mesh and is treated in 3 sizes. An iron-wolfram reject from the magnetic machines is tabled to recover wolframite.

The outstanding feature of the plant is the excessive number of settling boxes, entailing, as they do, great loss of head-room and, undoubtedly, much lost time in operation due to clogging of the spigot discharges. Modern practice would substitute mechanical classifiers or diaphragm cones for the sand-slime separation and Dorr thickeners for de-watering, thus greatly decreasing the number of such steps and simplifying the flow-sheet.



a, Wilfley and Buss types. *b, c, d, e, f, i, j*, See Table 88. *g*, Cones 4.75 ft. diam., 3.25 ft. deep. *h*, Box, 3 × 2-ft. × 6 in. deep with 80-mesh cloth bottom. Dewatered oversize removed periodically.

33. Selling ores and mill products

Some ores as mined contain sufficiently large quantities of valuable mineral per ton to make concentration unnecessary. Certain ores, notably those in which gold and silver are the only commercially valuable constituents, likewise are not subject to concentration. These ores and the concentrate produced in milling plants must be treated by some chemical process in order to obtain metals in a form useful in manufacturing and the arts. The gold and silver ores mentioned may be treated by the mining company, or, especially in case of small mines, may be sold to a custom milling plant. High-grade base-metal ores and mill concentrates are treated by smelting. Smelting plants usually buy the products that they treat, although occasionally contracts are made in which the smelting plant returns the metal recovered to the miner, making a charge for smelting.

Custom mills are built and operated in the same fashion as company mills. They differ from company mills only in that the mill equipment must be fitted to treat ores of somewhat diverse character, while the ordinary company mill is built to handle a special ore.

Methods of payment for gold and silver ores are simple. The ores are ordinarily shipped but short distances and are, consequently, all subject to substantially the same freight rate. In such case the custom mill makes a flat rate to cover freight and treatment and pays for the precious-metal content on the basis of agreed assays, less a flat rate covering freight and treatment, and of course, a certain profit on the transaction. Table 89 gives a

Table 89. Milling rates on Cripple Creek ores, including freight charge. (Full assay value in gold paid for at $20 per ounce)

Value of ore per ton	Charge per ton for treatment	Value of ore per ton	Charge per ton for treatment
Up to $10	$4.00	$25 to $30	$6.50
$10 to 15	5.00	30 to 40	7.00
15 to 20	6.00	Over 40	8.00
20 to 25	6.25		

typical schedule of custom-mill charges in the Cripple Creek district of Colorado in 1914. The charge increases with increase in value of ore. This is done in order to stimulate mining of low-grade ores and thus maintain a reasonably continuous supply of ore to the mill. High-grade ore is made to pay a greater profit than low-grade ore in order that a reasonable average profit may be maintained.

Smelters have a more complicated problem in the purchase of base-metal ores with or without a precious-metal content, consequently their schedules of charges and methods of payment are more complicated than is the case with custom mills. The smelter buys ores on the basis of the agreed assay, paying for valuable metals contained therein at prices current in principal metal-market centers, either at date of purchase or at some agreed date thereafter meant to be the probable date of sale, less a charge covering the cost of treatment and profit thereon. The treatment charge must include the cost of delivering ore to the smelter, sampling, smelting, freight on crude metal to the refinery, refining, selling, and a carrying charge on metal from the time of purchase to the time of disposal. Various methods of assessing these charges and the profit on operations are followed. In the case of some metals all is included in a treatment charge; in other cases a part only, namely, smelt-

ing, is included in the base treatment charge, the balance being taken care of in the price at which metal is paid for after certain deductions from the market price. Various methods are illustrated by examples on subsequent pages. All methods have as the fundamental basis of charge the cost of the various items above enumerated.

Freight is easily determined by reference to published tariffs available to the shipper. Rates per ton are usually higher, the higher the grade of ore. The quantity shipped, when less than carload lots, affects the rate. The charge is based on the gross weight at the shipping point while the smelter pays for dry ore, hence the less moisture in the ore as shipped the less the charge for transportation of water against dry ore. Moisture may run as high as 30 per cent. on some products, notably flotation concentrate, and as low as 3 or 4 per cent. on hard non-porous ores. (See also Sec. 23.)

Sampling. For discussion of methods see Sec. 21. Moisture samples should be taken as soon as possible after the ore is weighed in, especially if in open cars. Wetting after weighing in and before sampling results in a charge against the lot as weighed of too much moisture and hence operates against the shipper. Exposure to a hot dry atmosphere for a few days between weighing and sampling works similarly against the smelter. Sampling for chemical analysis should yield four final pulp samples; one for the smelter laboratory, one for the shipper, one for umpire, and one as an emergency reserve for either of the three. SPLITTING LIMITS between mine and smelter assays are given in Sec. 21, Art. 1. When umpiring is resorted to, the umpire's results are usually taken when they lie between the disputed results. The disputed result nearest the umpire's is taken when the umpire's result lies outside the disputed results. Analysis should determine not only the valuable metals but also constituents such as iron, lime, silica, magnesia, alumina and sulphur, upon which the common bonuses and penalties are based, and also any other substances that are specified in special instances. Analyses to determine these constituents should be just as carefully done as those for the valuable metals, as the penalty or bonus may make an important difference in the value of the ore. Silica should be determined by fusion rather than as "insoluble," as the latter is almost invariably high, as much as 15 to 20 per cent. with ores of high insoluble content and frequently 4 to 6 per cent. (*TP 83, USBM*). It is sometimes insisted also that iron and lime be determined by fusion. Ores that must be roasted and therefore crushed fine are usually sampled by machine, but those that are to be smelted in a blast furnace directly, such as oxide ores, are commonly sampled manually. The COST of sampling varies with the kind of ore and the method; it should rarely exceed \$1.00 per ton and averages near \$0.50 per ton with wages for common labor at \$4.00 per day.

Smelting is a chemical process in which reactions between various constituents present are brought about in a molten mass under the influence of heat. The method of smelting differs with the principal base-metal constituent of ore. When this is LEAD, the process consists essentially in mixing together a charge of such composition that when melted the worthless minerals will combine together to form a complex silicate, principally of iron and calcium, called SLAG, while metallic lead is freed and settles to the bottom of the molten mass, carrying with it in solution any precious metals present. If COPPER is also present it, together with some iron, combines with sulphur, forming an artificial copper-iron sulphide, called MATTE, that also settles out and comes to rest in the furnace between the lead and the slag. The various products are drawn from the furnace separately, slag is run to waste, lead is cast as crude lead, which must be refined in order to make it marketable and to recover the precious-metal contents, and the matte is further treated as described below to recover the copper and any precious metals present. In COPPER SMELTING a charge is similarly compounded to slag off the gangue and form matte that settles out, carrying with it precious metals. Matte is treated in a converter, a large pot in which the molten substance is subjected to air blown through in order to carry off sulphur in the form of

sulphur dioxide and leave crude copper containing varying amounts of iron, precious metals, etc. This crude or "blister" copper is cast into ingots and sent to the refinery where it is purified electrolytically. In ZINC SMELTING the ore, after being roasted to drive off sulphur, is placed with carbonaceous material in a retort and heated. Zinc is thus volatilized and passes into suitable collecting chambers, where it is condensed.

Penalties and bonuses. It is necessary in lead and copper smelting that the slag be sufficiently fluid to allow the metal or matte to settle out freely and to permit easy withdrawal of slag from the furnace. In order to obtain the desired fluidity the silicate formed must be of a particular composition. The basic smelter charge is founded upon the cost of smelting a charge of such composition and includes fuel, labor and all overhead costs. If the ore to be treated is not of the desired composition, it is necessary to make up any deficiency. In districts where the majority of the ores sent to the smelter are silicious, iron or lime, or both, must be added. In order to cover the cost of addition of such substances, a penalty is imposed for silica present in the ore bought. If, on the other hand, the prevailing ores of the district are calcitic or ferruginous, then silica must be added and iron and lime are penalized to make up the cost of such addition. When silica is penalized iron and lime are usually granted a corresponding bonus; silica is given the bonus when iron and lime are penalized. Penalties and bonuses are quoted at so much per unit. A UNIT is one per cent. or 20 lb. per ton (22.4 lb. per long ton). SILICA PENALTY ranges from 10¢ to 15¢ per unit for all excess over a stated amount, which should be that required for a self-fluxing charge; IRON BONUS ranges from 5¢ to 10¢ per unit in excess. A bonus is not ordinarily paid for LIME, but should be, especially when silica is penalized. One part of iron or lime fluxes one part of silica in copper smelting; in lead smelting, two parts iron and lime are required for one part silica. Hence in copper smelting the bonus for iron and lime should be equal to the silica penalty and *vice versa*. In lead smelting there is justification in a silica penalty higher than the iron or lime bonus. When silicious ores are wanted at a smelter a FLAT RATE may be made for their treatment in place of allowing a bonus for silica. In this case the charge usually increases with the grade of ore, as is the case at custom mills, and for the same reason. Table 90 shows such a

Table 90. Flat schedule for silicious ores in Colorado district (1914)

Value of ore per ton	Charge per ton for treatment	Value of ore per ton	Charge per ton for treatment
$14 and less	$5.00	$35 to $40	$8.00
14 to $20	6.00	40 to 45	8.50
20 to 25	6.50	45 to 50	9.00
25 to 30	7.00	50 and more	10.00
30 to 35	7.50		

schedule. In lead smelting, the formation of any considerable amount of matte is undesirable and consequently it is necessary to roast sulphide ores prior to their introduction into the smelting furnace. For this reason sulphur, being a source of expense to the smelter must be paid for by the ore seller and is usually charged in the form of a penalty for sulphur. The usual contract penalizes SULPHUR in excess of 2 or 3 per cent., ordinarily at a rate of 15 to 25¢ per unit. Sulphur is not penalized in copper smelting, since here it is desirable. ZINC, in lead and copper ores, causes slag to be thick and viscous, thus increasing metal losses therein and lowering furnace capacity.

It also causes fumes that foul the furnace walls, and, by volatilization, causes losses of other metals. For this reason, zinc over a certain amount is frequently penalized. Various forms of contract covering zinc in lead and copper ores are as follows: Penalty, 30¢ to 50¢ per unit for all excess above 10 per cent. (*TP 83, USBM*). Eight per cent. free, excess penalized at 30¢ per unit. Twelve per cent. free, excess penalized at 30¢ per unit (*85 J 992* [*1908*]). The limit may run as low as 5 per cent. and the penalty as low as 15¢ per unit. ARSENIC is decidedly undesirable in lead smelting and for that reason all over 1 per cent. is commonly penalized; ANTIMONY, BISMUTH and TIN are also objectionable; the penalty for these four combined may run as high as $1 per unit for the excess over 0.5 per cent. An arsenic penalty is less frequently imposed in copper smelting. Iron is highly undesirable in zinc smelting; more than 10 per cent. makes the ore substantially unfit for treatment. The PENALTY FOR IRON is normally imposed by setting a certain price for zinc ore of a given zinc content and penalizing it so much per unit for each unit below standard. In such cases a corresponding bonus is ordinarily given for each unit of zinc above standard.

Basic smelting costs. Walker (*Peele*) states that basic smelting costs as of 1926 for large plants are $3 to $5 per ton of charge in lead smelting and $2 to $3 in copper smelting.

The following are base charges for LEAD SMELTING taken from various contracts (*85 J 992* [*1908*]); (*a*) $7.50 per ton for all ores; (*b*) $7.50 per ton for ores carrying less than 25 per cent. lead, $7 per ton from 25 to 30 per cent. lead, $6.50 per ton for ores carrying more than 30 per cent.; (*c*) $8 per ton for ores carrying less than 30 per cent. of lead and $6 per ton for ores carrying 30 per cent. or more; (*d*) as in Table 91. These figures should be increased 30 to 50 per cent. for 1926. Usually the smelting cost per ton decreases with increase in grade, because there is less gangue to be slagged off in the higher-grade ores, hence less fuel need be used per pound of metal produced; furnace capacity is higher so that labor cost and overhead per pound of metal produced are lower.

Table 91. Schedule of treatment charges on lead ores

Lead content, per cent.	Treatment charge, dollars per ton	
	Contract A	Contract B
5 to 10	7.25	9.00
10 to 15	6.00	8.00
15 to 20	5.00	7.00
20 to 25	4.00	6.00
25 to 30	3.00	5.00
30 to 35	2.25	4.00
35 to 40	1.35	3.00
40 to 45	0.50	2.00
Over 45	0.00	1.00
45 to 50	0.00	....
50 to 55	Bonus 0.75	....
Over 55	Bonus 1.25	....

A common basic charge for COPPER ORES is $4 to $4.50 per ton.

Freight on crude metal, refining, and selling are usually taken care of in smelter contracts by deductions from the price per pound paid for metal. The costs (1926) of these various operations, according to Walker (*Peele*) are:

for refining lead, \$8 to \$12 per ton of bullion; for converting copper matte, about \$10 per ton of blister copper produced; for refining copper, \$15 to \$23 per ton of bullion. The usual deduction in copper contracts is 3¢ per lb. from the New York quotation for electrolytic copper. Similarly from 1 to 1½¢ per lb. is deducted from the lead price.

Losses include metal in slags, either as shot or combined, and losses by volatilization. Walker gives the following metal losses in smelting and refining; lead, 4 to 15 per cent., depending upon the grade of ore and its refractoriness; the lower limit is for a charge carrying about 40 per cent. lead; the higher, for one carrying 10 to 12 per cent. lead. Copper loss sometimes reaches 30 per cent. in lead smelting. In smelting copper ore the loss varies with the percentage of copper, but is always much less than the loss of lead in lead smelting. Silver loss is normally not over 2 to 5 per cent. Gold loss is not generally considered.

Fulton (*T. P. 83, USBM*) gives the following actual losses based on studies of smelter performances. In LEAD SMELTING: lead, 5 to 20 per cent. of contents, the low figure on a high-lead charge, 30 to 35 per cent. or upwards, and containing but a small amount of roasted material; the higher, on a charge containing less than 10 per cent. lead or a large amount of roasted material. Normal loss with a charge containing 10 to 15 per cent. lead is 8 to 11 per cent. Copper, 1½ to 4 lb. per ton of charge. Silver, 1.5 per cent. loss to 1.75 per cent. gain. The gain is, of course, apparent only, and follows from the practice of charging the smelter with silver only in those ores containing more than a certain minimum amount. Gold, 0.3 per cent. loss to 4.5 per cent. gain. The gain here also is apparent only and arises from the same reason as given for apparent gain in silver. In COPPER SMELTING: copper, 3 to 11 lb. per ton of ore smelted or 5 to 15 per cent. on the copper present, the higher figure on the lower grade ore. Silver, 0.5 to 10 per cent. of contents. Gold, 1.5 per cent. loss to 4 per cent. gain. Barbour (*92 J 314*) states that the silver loss in good lead smelting should not exceed 3 per cent. He says the usual zinc loss in ZINC SMELTING is about 12.5 per cent.

Lead losses are sometimes taken care of, wholly or in part, by basing payment for lead on a fire assay. This practice is based on the assumption that fire assaying is smelting on a small scale and recovers the same amount of lead that will be recovered in the furnace. The fire assay for lead runs about 0.5 to 1 per cent. below the wet assay unless such metals as zinc, copper, antimony, bismuth or arsenic are present, in which case fire assay man run high. To cover this contingency some contracts call for wet analysis of the button obtained by fire assay and base lead payment on the assay thus obtained. Common practice at present is to make wet analysis and deduct therefrom 1 to 1.5 per cent., calling this DRY ASSAY or FIRE ASSAY and use it as basis for settlement. On the basis of a 10-per cent. loss of lead in smelting a 1.5-per cent. deduction from the wet assay more than covers the loss on ores carrying less than 15 per cent. lead but does not cover with higher-grade ores. However, the loss on higher-grade ores is a smaller percentage of the total lead present and it is probable, therefore, that a deduction of 1.5 per cent. from the wet assay more than covers loss in all cases of gold lead-smelting practice. Lead losses are further taken care of by paying for less than the whole amount of lead determined by either method of assay as, for instance, by paying for 90 per cent. of the lead determined by dry assay. Further, the deduction from the market price is oftentimes made greater than the cost of freight on crude metal, refining, and selling, in order to further insure the smelter against losses.

Copper losses are similarly taken care of, although the use of the dry assay is less common than with lead. "Dry copper" means from 0.75 to 1.5 per cent. less than the wet assay.

Gold and silver losses are provided for by deducting up to 5 per cent. of the assay value for gold and 5 to 10 per cent. for silver, or by paying less than the full price for all of the metal present, or both.

Value of ore is stated in some monetary unit per unit of weight. In the United States the respective units are dollars and short tons; in most British possessions shillings and long tons; in certain Latin countries, the metric ton may be used with the local monetary unit. Locally almost any system of stating value may be met. Value is determined by multiplying together units of weight of valuable material per ton by price per unit of weight at some accepted market center, usually New York, and deducting from the product thus obtained the cost of producing refined metal from a ton of ore and the price of the valuable material lost in the operation. MARKET PRICES of metals vary widely. Ranges and averages are given in this section. The unit of weight for precious metals in the United States is the

troy ounce; in other countries pennyweight, grain, or gram may be used. English-speaking countries use pound or ton as the unit for base metals; countries using metric system employ metric units.

Payment for metals

Gold is usually paid for at from \$19 to \$20 per oz. for all gold, if in excess of some certain minimum, usually, from 0.02 to 0.05 oz. per ton. Oftentimes the contract calls for payment for only the excess of gold over the minimum. The price may vary according to the amount present, thus \$19 per oz. may be paid for all of the gold or the excess over the minimum amount, if the total amount is less than 0.25 oz.; \$19.50 if the total amount is between 0.25 and, say, 1 oz.; and \$20 per oz., if the total present is more than 1 oz.

Silver. The usual form of contract is to pay for all silver at 95 per cent. of New York quotation at some date ranging from the time of purchase to, say, 3 or 4 months thereafter. The assumption is, in case of deferred payment, that the smelter does not then have to gamble on the price of metal at the time that it is sold and that consequently the price paid to the shipper, or the amount of metal paid for, or the treatment charge, can be so adjusted as to repay the shipper for taking the risk of price fluctuation. Another common form of contract is to pay for 90 to 95 per cent. of silver present at 90 to 95 per cent. of the New York quotation at the date agreed upon. Of course, in this form of contract, the smelter is more liberally insured against losses and more liberally paid for recovery of silver than in the first form of contract. If such a contract is made, a corresponding advantage should accrue to the shipper in some other part of the contract.

Lead. Three methods are followed in paying for lead.

METHOD No. 1. Payment is made on the basis of the wet assay less 1 to 1.5 per cent. at certain prices per unit arrived at by the following method. First, a certain base price per unit, varying with the metal content and with a QUOTATION is set.

Quotation is 90 per cent. of New York price when this is \$4 per 100 lb. of lead or less If the New York price is between \$4 and \$4.50, the quotation is 90 per cent. of \$4 plus one-half of the excess of price over \$4. If New York price exceeds \$4.50, the quotation is 90 per cent. of \$4 plus half of the excess between \$4 and \$4.50 plus all of the excess over \$4.50. Table 92 presents a set of prices based on a quotation of \$4 per 100 lb. of lead. For each change of 5¢ in quotation a corresponding change of 1¢ is made in the price per unit.

Table 92. Unit prices for lead on "Quotation" of \$4 per 100 lbs.

Lead content of ore, dry basis, per cent.	Price per unit (*a*)	Lead content of ore, dry basis, per cent.	Price per unit (*a*)
5 to 10	\$0.35	25 to 30	\$0.49
10 to 15	0.40	30 to 35	0.51
15 to 20	0.45	Over 35	0.51
20 to 25	0.47		

a Unit equals 1 per cent., or 20 lbs. per ton.

Example: Ore contains 40 per cent. lead by wet assay and New York price is \$4.40 per 100 lb. Quotation is $0.90 \times (\$4)$ plus $0.5 \times (\$4.40 - \$4) = \$3.80$. This is 20¢ below the quotation on which Table 92 is based, hence 4¢ must be deducted from the price per unit in the table, corresponding to a dry assay of 38.5 per cent. The price paid per unit is, therefore, 47¢. The lead paid for is 770 lb. per ton. The price paid per ton is $(770/20) \times 0.47 = \$18.09$. On a New York price of \$5, the quotation would be $0.90 \times (\$4) + 0.5 \times (\$4.50 - \$4) + 0.50 = \$4.35$; the price per unit would be \$0.58, and price per ton \$22.33.

METHOD No. 2. Payment is usually for 90 per cent. of the fire assay at from 1¢ to 1.5¢ per lb. off New York price, usually the higher figure if the ore carries 5 to 25 per cent. lead and 1.25¢ if the ore carries over 25 per cent. lead. Less than 5 per cent. of lead is not paid for. In some cases as much as 1.75¢ is deducted from New York price.

METHOD No. 3. Payment for 90 per cent. of fire assay at from 90 to 95 per cent. of New York price. Less than 5 per cent. of lead is not paid for.

BONUS FOR LEAD may be allowed on ores carrying less than 5 per cent. This bonus is usually at the same rate as that for iron, but may run up to 15¢ per unit where iron pays only 10¢ per unit.

In some cases a fixed price is set for lead equivalent to a deduction of from 1.5¢ to 2¢ per lb. from the probable average New York price over the term of the contract. This, of course, puts the burden of fluctuation in lead prices on the smelter and the deduction from the probable market price is, therefore, greater than would be the case, if the risk of fluctuation were carried by the seller. Such a method of payment is rarely introduced into large contracts, but is used with small shippers who desire to know definitely at time of sale what the receipts from the shipment will be.

Lead schedules. The following schedules are typical:

Schedule No. 1. Allow: Gold, if 0.1 oz. or over, $19 per oz. for full assay; silver, if 1.5 oz. or over, 95 per cent. at New York quotation on date of assay; lead, if 5 per cent., 50¢ per unit on quotation of $4 per 100 lb with variation of 1¢ per unit for every 5¢ change in quotation. (This is method No. 1 above); iron, pay for all at 4¢ per unit; lime, pay for all CaO at 6¢ per unit, if over 5 per cent, except that lime combined with fluorine is not paid for. Deduct: all insoluble at 10¢ per unit; sulphur, 1 per cent. free, excess at 50¢ per unit; arsenic, antimony and bismuth, if a total of 3 per cent. or over is contained, all at 50¢ per unit. Base charge, if 5 per cent. of lead or under, $5 per ton of 2000 lb.; if over 5 per cent. lead, deduct 10¢ per unit for each unit of lead in excess. Sampling, free on lots over two tons; $3 per lot, if under 2 tons. Add $1.50 per ton for concentrates or ores requiring briquetting. Moisture, 1 per cent. minimum in all cases (*Mines and Methods*, Nov., 1909).

Schedule No. 2. Utah, in the neighborhood of SALT LAKE. Pay for all gold at $19 per oz. and all silver at 95 per cent. of New York price at date of assay. Pay for 90 per cent. of lead by fire assay, at New York price less 1.25¢. Pay for iron at 10¢ per unit and impose a penalty on silica of 12¢ per unit. Treatment charge, $2.50 per ton for 30-per cent. lead ore with a credit of 5¢ per unit for each unit of lead in excess and a penalty of 8¢ per unit for each unit deficit (*92 J 314*).

Schedule No. 3. LEAD-SILVER ORE Pay for 85 per cent. of lead on fire assay at 85 per cent. of New York price, if New York price is $4 or less; if more than $4, pay 85 per cent. of $4 plus one-third of difference between $4 and New York price. Pay for 95 per cent. of silver at 95 per cent. of New York price. Treatment charge, including freight, for ore containing 45 per cent. lead, $10, with 10¢ per unit penalty for lower lead content and corresponding bonus for excess.

Schedule No. 4. TRAIL, B. C. Base, $8.50 to $9.50 per ton for 70 per cent. lead ore plus 10¢ for each unit under 70 to a maximum of $10.50 to $11.50. The lower rate is the contract rate and the higher, the open rate. Lead, if over 5 per cent., is paid for on the basis of 90 per cent. of fire assay at the London price less 1¢. 95 per cent. of gold is paid for at $20 per oz. All silver is paid for at 95 per cent. of New York quotation (*92 J 314* [1911])

Schedule No. 5. Pay for 90 per cent. of lead at St. Louis price less a treatment charge of $6 to $8 per ton of ore (*92 J 314* [*1911*]).

Schedule No. 6. NEUTRAL SCHEDULE, used chiefly in COLORADO. Gold, $19.50 per oz., if 0.05 oz. or over per ton. Silver, 95 per cent. of contents at New York quotation, date of assay. Lead (dry), as in No. 7, prices based on "quotation" of $4. Copper: for dry copper (1.5 per cent. off wet), at 6¢ off per lb. on Western Union quotation for casting copper. Zinc, 10 per cent. allowed; 50¢ penalty per unit for zinc in excess of 10 per cent. Silica penalty, 10¢ per unit; iron bonus, 10¢ per unit.

Schedule No. 7. NEUTRAL SCHEDULE used in UTAH. Credits: Gold, $19 per oz. if the product contains 0.03 oz. or over per ton. Silver, 95 per cent. of contents, at New York quotation, date of assay. Copper, as per wet assay, less 1 per cent. or unit, at the price for cathode copper quoted in the *Engineering and Mining Journal-Press*, issue of the week previous to date of receipt, less 5¢ per lb. Lead, 90 per cent. of contents (dry assay) to be paid for at the quotation in the *Engineering and Mining Journal-Press*, issue of week previous to date of arrival, less 1.25¢ per lb. Iron, paid for at 10¢ per unit. Charges:

Insoluble, 12¢ penalty per unit. Zinc, 10 per cent. allowed free; excess at 30¢ per unit penalty. Speiss (arsenic), 10 per cent. allowed free; excess at 20¢ per unit. Sulphur, 25¢ penalty per unit; maximum penalty imposed, $2.50 per ton. Treatment charge, $2 per ton, based on an ore carrying 30 per cent. lead; for each unit of lead above 30, a credit of 5¢ to be allowed; for each unit of lead below 30, a charge of 8¢ to be made.

Schedule No. 8. FLAT SCHEDULE. Payment made on metals as in Table 93.

Table 93. Flat schedule for lead in lead ores and lead-copper ores

Lead content, per cent.	Value per unit	Smelting charge, per ton	Lead content, per cent.	Value per unit	Smelting charge, per ton (a)
5 to 10	$0.40	$10.00	35 to 40	$0.52	$2.00
10 to 15	0.43	8.50	40 to 45	0.52	1.00
15 to 20	0.45	7.00	45 to 50	0.53	1.00
20 to 25	0.47	5.50	50 to 55	0.54	1.00
25 to 30	0.49	4.50	Over 55	0.55	1.00
30 to 35	0.51	3.50			

a For concentrate containing more than 30 per cent. lead, apply flat schedule, as above, or neutral schedule, Table 95, whichever will give a larger return to the shipper, except that a gold content of 0.05 ounce to 2 ounces is at $19 and a content of more than 2 ounces at $19.50.

Schedule No. 9. For LEAD CONCENTRATE. Gold, $19 per oz. when gold content is 0.05 to 2 oz. per ton; when content is more than 2 oz., $19.50 per ton. Silver and copper, as in neutral schedule, Table 94. Lead, as in Table 95, prices based on "quotation" of $4. Silica, limit, 10 per cent.; 10¢ penalty for each unit in excess of 10 per cent. Zinc, limit, 10 per cent.; 50¢ penalty for each unit in excess of 10 per cent.

Table 94. Neutral schedule for lead in lead ores and lead-copper ores

Lead content, per cent.	Value per unit	Smelting charge per ton (a)	Lead content, per cent.	Value per unit	Smelting charge, per ton (a)
5 to 10	$0.40	$6.00	35 to 40	$0.52	$1.50
10 to 15	0.43	5.00	40 to 45	0.52	1.00
15 to 20	0.45	4.00	45 to 50	0.53	1.00
20 to 25	0.47	3.00	50 to 55	0.54	1.00
25 to 30	0.49	3.00	Over 55	0.55	1.00
30 to 35	0.51	2.00			

a Includes freight charge from a certain district in Colorado, a comparatively short distance from the smelter.

Table 95. Schedule for lead in lead concentrate

Lead content, per cent.	Value per unit	Smelting charge, per ton	Lead content, per cent.	Value per unit	Smelting charge, per ton
5 to 10	$0.40	$3.75	20 to 25	$0.47	$2.25
10 to 15 *a*	0.43	3.00	25 to 30	0.49	2.25
15 to 20	0.45	2.50			

a More than 10 per cent.

Copper schedules. Payment is made on the basis of the wet assay less from 1 to 1.5 per cent. at prices representing certain deductions from New York prices for refined copper. New York quotations are for three grades: electrolytic copper, as ingots or wire bars; cathode copper, which is electrolytic

copper not re-melted into ingot form; and casting copper, which is not electrolytically refined. Cathode copper sells at about 0.1¢ less and casting copper at about 0.2¢ less per lb. than ingot copper. The usual smelter deductions

Table 96. Smelter deductions from market prices for copper

Kind of ore	Copper content of ore (a)	Deductions per pound
Lead ore containing copper...	1.5 to 5	6 cents off casting-copper quotation
	5 to 10	5 cents off casting-copper quotation
	More than 10	4 cents off casting-copper quotation
Copper ores..................	1.5 to 5	5 cents off electrolytic-copper quotation
	5 to 10	4½ cents off electrolytic-copper quotation
	10 to 20	4 cents off electrolytic-copper quotation
	20 to 30	3½ cents of electrolytic-copper quotation
	More than 30	3 cents off electrolytic-copper quotation

a Dry copper content represents content as determined by wet analysis less 1.5 per cent.

from the price paid for copper in lead and copper ores are shown in Table 96 (*TP 83, USBM*). The following are typical schedules.

Schedule No. 1. UTAH contract. Pay for all copper shown by wet assay less 1 per cent. at New York quotation for electrolytic wire bars less 2.5¢. 1 per cent. off selling price for selling. Base charge, $2.30 per ton of ore. Silica penalty, 12¢ per unit. Iron bonus, 10¢ per unit. Freight charge, on sliding scale (this is for camps in the region surrounding the smelter) as follows: Net value of ore after all deductions under $10, $1.75 per ton; $10 to $20, $2 per ton; $20 to $30, $2.50 per ton (*92 J 314* [*1911*]).

Schedule No. 2. Schedule on copper ores containing gold and silver: NEUTRAL SCHEDULE. Credits: Gold, $19 per oz. if product contains 0.03 oz. or over per ton. Silver, 95 per cent. of contents at New York quotation, date of assay. Copper, as per wet assay, less 1 per cent. or unit, at price for cathode copper quoted in *Engineering and Mining Journal-Press*, issue of week previous to date of receipt, less 2.5¢ per lb. Iron, paid for at 10c per unit. Charges: Insoluble, 10¢ penalty per unit. Zinc, 10 per cent. allowed free; excess at 25¢ per unit. Speiss (arsenic), 10 per cent. allowed free; excess at 25¢ per unit. Treatment charge, $3 per ton.

Table 97 summarizes copper-smelting contracts at various North American smelters.

Zinc Schedules. (*92 J 314* [*1911*]) Middle West zinc ores are usually bought outright by smelters and ore buyers on a base price for 60-per cent. sulphide ore or 30-per cent. carbonate ore with a penalty of $1 for each per cent. below the base and a bonus of the same amount for each per cent. above. In some cases a penalty is imposed for iron and in some also for lead. The iron penalty may run as high as $1 for each unit in excess of one. Lime also is sometimes penalized. Wisconsin carbonate zinc-ores, which are sold on a base of 30 per cent. zinc, carry a premium of 65¢ per unit in excess. Base prices are quoted in mining journals weekly.

Sliding scale for zinc has been tried, but was not favored by the miners. It was based on a price per ton of blende containing 60 per cent. zinc, less than 2 per cent. iron and 5 per cent. lead, of $37 to $41 per ton with spelter at 5¢ at St. Louis. A penalty of $1 per unit of zinc was imposed for each unit under 60 and a corresponding bonus allowed for each unit in excess of 60. The base price increased or decreased $8.50 per ton, respectively, with each corresponding difference of 1¢ in price of spelter (*92 J 314*).

European zinc-ore purchases are made by a formula $V = 0.95\ P(T - 8)/100 - R$, where V = the value per ton in any monetary unit, P = price of spelter at London in the same unit, T = units of zinc, and R = treatment charge in the monetary unit adopted.

Australian zinc ore. At BROKEN HILL zinc ores are penalized if they contain less than 5 per cent. of lead; nothing is paid for lead between 5 and 8 per cent.; a bonus is paid, if lead is in excess of 8 per cent.

Table 97. Summary of various

Plant	A	B	C	D
Gold	$19 per oz. if under 0.5 oz. per ton. $19.50 per oz. if over 0.5 oz. per ton.	All at $20 per oz. if over 0.5 oz. per ton. No payment for less than 0.5 oz.	95% at $20 per oz.	$19 per oz.
Silver	90% at New York quotation. No payment for less than one oz. per ton.	95% at New York quotation.	90% at New York quotation.	90% at New York quotation.

E is a Southwestern plant. F is a Northwestern plant. G, H, I are Utah smelteries.

Silver ores. Table 98 (*92 J 364*) gives special schedules for treatment of silver ores from the Cobalt district. These ores are high-grade and contain large amounts of cobalt, nickel and arsenic. The schedules are special schedules for this particular type of ore. Most silver in this country is recovered by amalgamation and cyanidation or as a by-product in smelting base-metal ores and concentrates.

Table 98. Summary of schedules for Cobalt silver ores (*92 J 364*)

Plant	Balbach Smelting and Refining Company	Pennsylvania Smelting Company	Beer, Sondheimer and Co.
Silver	Pay for 93.5% at New York quotation.	95% at New York quotation less 1¢ per oz. for refining.	94% at New York quotation.
Arsenic	Penalty of 45¢ per unit in excess of 6.	....	....
Insoluble	Penalty of 6¢ per unit in excess of iron.	....	....
Treatment charge	$4 per ton on ores containing 1000 to 1500 oz. Ag. $20 when 1500 to 2000 oz. $19 when over 2000 oz.	$8 per ton.	$30 per ton.

Plant	Canadian Copper Company		Coniagas Reduction Company		Delora Mining and Reduction Company

SECTION 3

COARSE AND INTERMEDIATE CRUSHING

CRUSHING PLANTS

1. Introduction

Ore invariably comes from the mine in lumps that are large in comparison to those that are amenable to concentration of any kind other than hand sorting. Crushing is, therefore, a part of all flow-sheets. Further, since the method of crushing, at least in the larger sizes, has little or no effect on the character or performance of the subsequent mill processes, crushing flow-sheets may be studied without regard to the mineral content of the ore.

The determining elements in every coarse-crushing flow-sheet are: (1) the nature of the material, especially as regards hardness and moisture content; (2) the dimensions of the largest lumps of run-of-mine ore; (3) the size of the largest particles that are to be sent to the fine-crushing plant; (4) the tonnage to be treated; (5) the daily running time; and (6) the location with respect to the mine and the balance of the mill. Table 1, arranged from a study of the effects of explosives on rocks (*Snelling, 28 Pro. Eng. Soc. W. Pa., No. 8*) is useful for estimating probable relative resistance to coarse crushing. The arrangement of machines will be affected by the type of plant construction, the kind of power and the method of distribution, and by considerations of accessibility and consequent economy of operation and maintenance. As a general principle, all crushers should have receiving openings of sufficient size to take the largest lump of feed without any aid from the operator, but under certain circumstances this rule may be departed from in the case of the initial crusher, which must have an operator continuously in attendance anyway to pick out powder, wood, rope ends, steel, etc., and this operator may be called upon to sledge an occasional oversize lump. The ratio of size of the largest lump entering the plant to that of the largest particle leaving determines in a general way the number of steps in the size reduction. Best practice rarely exceeds a reduction ratio of 4 : 1 in maximum size and ratios

of 3 : 1 and 2 : 1 are common. The number of hours per day during which ore is delivered from the mine, the storage and handling facilities, the daily and hourly tonnage, and the facilities for repairs, influence both size of machines and the number of reduction steps. Few underground mines hoist during all three shifts and few hoist continuously during the hoisting shifts. In many, if not most open pits, loading takes place only during daylight. Hence, unless ample storage is provided between the mine and coarse-crushing plant (and bin storage of this material is avoided where possible because of the tendency of coarse ore to clog in gates and chutes of any reasonable size) the capacity of the plant must be adapted to the rate of ore delivery from the mine. This calls for machines whose hourly capacity is from 1½ to 3 times that of the fine-crushing and concentrating equipment and for the provision of sufficient storage capacity between the coarse-crushing plant and mill proper to equalize the flow over 24 hr.

Table 1. Relative toughness of rocks and their resistance to fracture. (*After Snelling*)

Rock	Relative toughness (limestone = 1)

Coarse-crushing machinery is subject to enormous strain and considerable wear, and, notwithstanding its rugged character, must frequently be shut down for repairs. For this reason and in order that the shut-downs may not interfere either with mining or milling operations, the size and number of machines is usually such that part-time operation only is necessary to crush the daily tonnage, thus affording time for daily inspection and the making of minor repairs.

2. Flow-sheets

Examples of several types of coarse-crushing flow-sheets are given in Figs. 1 to 20, incl. These are all large-capacity plants, planned for one- or two-shift operation. (For examples of smaller plants see the flow-sheets in Sec. 2.) The flow-sheets fall naturally into two groups, depending upon the size of feed, which, in turn, depends upon the method of mining. When the feed is extremely coarse and bouldery, the product of steam-shovel mining, the plants contain two breakers of the jaw or gyratory type in series, followed by one or more intermediate crushers of the roll or disk type. With relatively fine feed (−18-in. or smaller), the product of underground mining, one of the breakers is frequently dispensed with, the rest of the plant being of the same general character as the plants for steam-shovel mines. Most of the plants close the circuit on the last intermediate crusher with a screen to insure that all of the material in the bins is less than the desired limiting size. The plants

at underground mines usually interpose a bin between the skip dump and the primary crusher. This permits steady feed to the primary crusher and hence to the balance of the plant, and smaller crushers can be used than if they were to be intermittently buried under an avalanche of several tons from the dumping skip. At steam-shovel plants bins are not ordinarily used ahead of the primary crusher because of the great difficulty of moving large lumps through the gates without excessive clogging. Hence the primary crusher at these plants must have a receiving opening large enough to take the largest lumps that the steam shovel can handle, and with these lumps the major part of the quarry-car load, and must be able to keep on crushing steadily when the receiving opening is buried. The primary requirements of such a crusher are, therefore, a large receiving opening and ability to utilize large overdrafts of power. It is rarely that the capacity required is greater than that of a jaw crusher of the necessary area of receiving opening and for this reason jaw crushers are usually placed in this position (see also Art. 9).

3. Steam-shovel mines

Plants characterized by direct feeding from cars and the use of two breakers in series.

Valhalla crushing plant, N. Y. City Water Supply. Fig. 1. (*36 MEW 451.*)

Capacity: 500 cu. yd. per hr. (est.)

Summary. No receiving bin. Jaw crusher, 60- to 9-in.; jaw crusher, 9- to 4-in.; rolls, 4.5- to 2-in. Rotary screen to close the circuit on the rolls. Bucket elevator.

The unusual feature of this plant is the use of a jaw crusher for the second crushing unit. A gyratory crusher of equal weight has greater capacity, smaller power consumption per ton crushed and a more favorable nip angle. The only apparent reason for use of the jaw-type machine is that it saved considerable head room and made it unnecessary to sink the elevator boot pulley any deeper into the ground. Since the plant was a temporary one, built to work only during the building of the Kensico dam, it may be that the higher running expense and greater initial cost of the jaw crusher were more than offset by the saving on the elevator. The lack of balance in reduction ratios in large and small jaw crushers is due to the inadequate capacity of the second crusher. To most designers the use of a bucket elevator for such coarse material is poor practice. It is true that its use gave a more compact and probably less expensive plant than would have been possible had belt conveyors been used for elevation (Fig. 2), but almost universal experience shows that the conveyors would have been cheaper and smoother in operation. The bin and pan conveyor ahead of the rolls are excellent design, insuring, as they do, against overfeeding and equalizing, to a certain extent, the fluctuations in tonnage rate incident upon intermittent feeding of carload lots to the primary crusher.

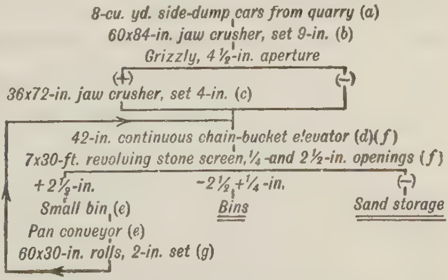

Fig. 1.—N. Y. City Water Supply, Valhalla crushing plant.

a, Dumped one at a time directly into the crusher jaws. *b,* Rope drive (sheave with 15 @ 1½-in. grooves, tension carriage and idler sheave) from a jack shaft belt-driven through a friction-clutch pulley from a 300-hp. @ 560-r.p.m. mill-type slip-ring induction motor with 250 per cent. full-load starting torque. Crusher, cast-steel; weight, 450,000 lb. Flywheels, 12 ft. diameter; weight, 15 tons each. Manganese-steel jaw and cheek plates in interchangeable sections. All bearings water cooled. Speed, 90 r.p.m. *c,* Cast steel. Weight, 210,000 lb. 200 r.p.m. Motor, 150-hp. @ 560-r.p.m., same type as above, belted

direct to crusher with 20-in. endless double-leather belt. *d*, Buckets, 42 × 18 × 19-in. of ¼-in. pressed steel with ¾ × 2-in. reinforcing bar strap, each carried on a shaft with steel-bushed rollers that travel on 30-lb. rail. Roller-shafts linked by double bars, ½ × 3 × 18-in., each side. Speed, 95 ft. per min. *e*, To equalize roll-feed rate. *f*, Elevator and trommel driven by a 50-hp. @ 850-r.p.m. squirrel-cage induction motor. *g*, Smooth shells, 50 r.p.m. Capacity, 300 cu. yd per hr. from 4-in to 2-in. Motor, 100-hp., 560-r.p.m., same type as crusher motors.

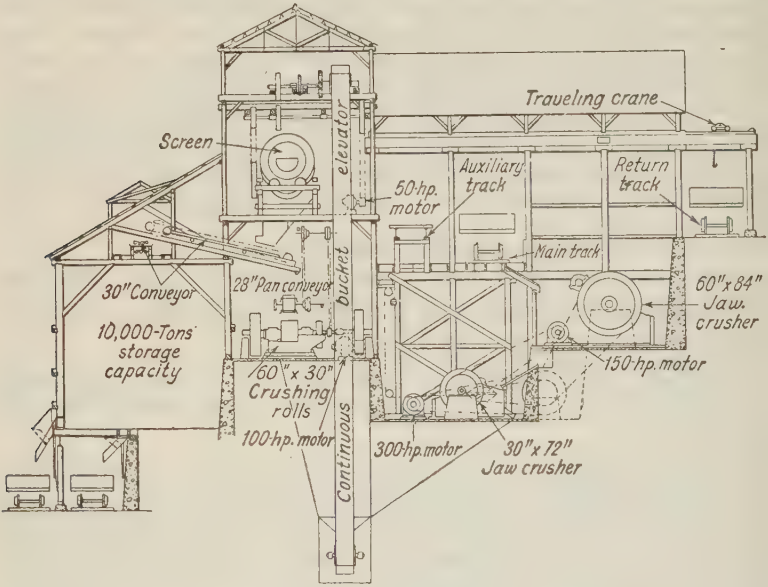

FIG. 2. —Elevation of Valhalla crushing plant.

New Haven Trap Rock Co., North Branford, Conn. Fig. 3. (*73 EN 582.*) Crushing trap rock from steam-shovel size to −2-in. at 350 to 400 tons per hr., 1-shift operation. Diagrammatic layout of plant is shown in Fig. 4.

Summary. No receiving bin. Jaw crusher, 48- to 10-in.; gyratory, 10- to 5-in.; gyratory, 5- to 1.75-in. Circuit closed by revolving screen and disk crusher. All plant transport and elevation by belt conveyors.

This flow-sheet shows the more usual arrangement for medium-large tonnages, *i.e.*, a large jaw crusher for the initial machine followed by a gyratory. The weight of these two crushers is less than that of jaw crushers for the same crushing capacity and the power consumption per ton crushed is also less. The arrangement that allows either of the first two crushers to be cut out without stopping the whole plant (see Fig. 4) is admirable. The great bulk of the crushing is done in the jaw and gyratory crushers and but little load goes to the disks, which serve essentially merely as accessories to the secondary gyratories, with the advantage, however, that they may be set down to increase, slightly, the tonnage of finer sizes, when there is such a demand. The four No. 6 gyratories are used in this plant to do substantially the same work done by one set of 60 × 30-in. rolls at the Valhalla plant. The gyratories weigh more, require more power and more transmission machinery, and probably, on the whole, cost more for repairs. They have the advantage that plant operation does not have to be stopped completely while repairs are being made, as is the case with the single-roll unit at Valhalla.

a, Dumped one at a time directly into jaws of primary crusher. Can be dumped into gyratory, if desired. *b*, 250-hp. motor drives jaw crusher, primary trommel and 30- and 36-in. conveyors; crusher draws 200 hp. Lenix drive, 10-ft. centers. *c*, Jaw crusher can discharge directly to 36-in. conveyor. *d*, 150-hp. motor. *e*, 150-hp. motor for the four. *f*, No. 2 trommels and 20- and 24-in. conveyors driven by 1 @ 75-hp. motor. *g*, Setting varied according to sizes of finished rock in demand. 1 @ 100-hp. motor. *h*, 20- and 30-in. conveyors and 6 screens driven by 150-hp. motor. *i*, 6-compartment, 3000 cu. yd. total capacity. Loads directly to cars through tilting chutes on the front or through bottom gates and an inclined conveyor to an auxiliary loading bin. (See Fig. 4.) The shipping yard has trackage for 40 @ 50-ton standard-gage empties ahead of the loading point and 40 loaded cars following. Cars move by gravity from empty yard to loaded yard. Tidewater shipping bins 6 miles distant by privately owned, single-track railroad. *j*, All screen jackets of manganese steel.

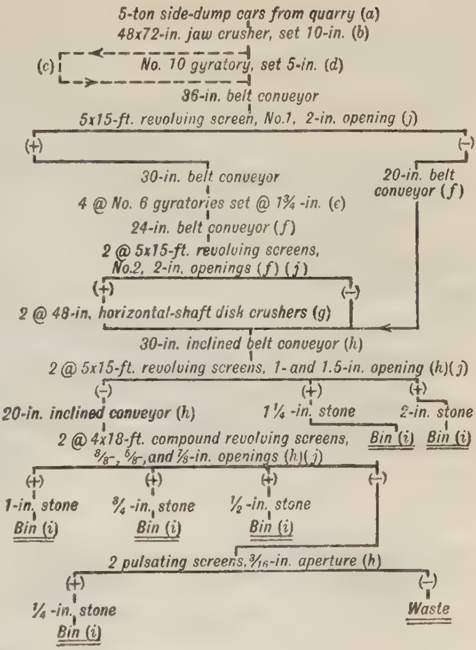

FIG. 3.—New Haven Trap Rock Co.

New Cornelia Copper Co., Ajo, Ariz. Fig. 5. (*108 J 465.*)

Crushing hard, bouldery ore from 4½ × 4½ × 10-ft. maximum to ¼-in. at 400 to 500 tons per hr., 2-shift crushing.

Summary. No receiving bin. Gyratory, 54- to 6-in.; gyratory, 9- to 3-in.; disk, 3- to 0.75-in.; disk, from 0.75- to 0.38-in. Circuit closed on final disk by means of screens. Coarse-ore transport by belt conveyors, −0.75-in. product raised in bucket elevator.

The primary gyratory was oversize for this plant when making the normal reduction to 8- or 9-in. and reduced a carload of material so rapidly that it flooded the secondary gyratories. The primary machine was, therefore, made to do more work by reducing the discharge opening to 6 in., thereby relieving the secondary machines, but, more important yet, distributing the feed to the secondary machines over a greater part of the total working time. Considerable trouble is caused by lumps too large to enter the primary machine. On the information available it would appear that a 60 × 84-in. jaw crusher followed by a flow-equalizing bin and feeder would give more satisfactory service at less cost than the big gyratory. A grizzly was subsequently put in ahead of the secondary gyratories and its use cut the repair costs on these machines materially.

The choice of disk crushers was dictated in part, at least, by the fact that the final product of these machines contained less fine material than that from rolls and the coarser product was more desirable for leaching. Comparing the product of this plant with that of the Utah Copper Co. rolls, the −20-mesh material in −⅜-in. screen product amounts to only 19 per cent. against 15 per cent. in the −1-in. product of the Utah plant.

In general disks cost more in supplies and time lost for repairs than do rolls, and they are frowned upon by many designers on this account. For coarse feeds and relatively small tonnages per unit, however, the weight and power consumption are so much smaller than for rolls that the disks are entitled to serious consideration.

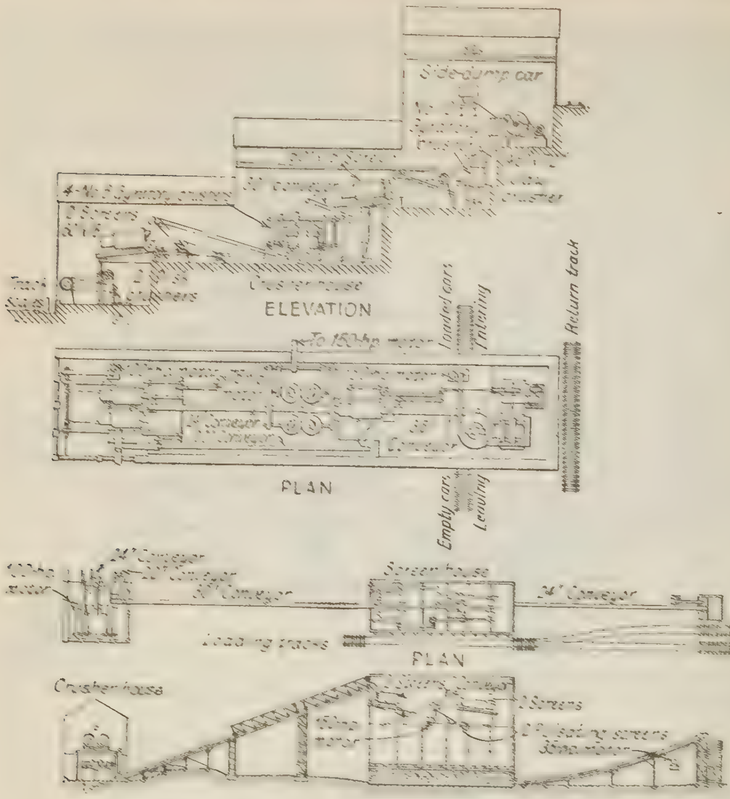

FIG. 4.—Plant of New Haven Trap-rock Co.

The use of bucket elevators here to handle −0.75-in. dry material is a relic of disappearing practice. While data are not available to support the statement, it is a safe prediction that the excess of lost time and repair charges due to the elevator over that due to belt conveyors in the same position, will, in the life of the plant, much more than counterbalance the excess in first cost that would have attended a conveyor installation.

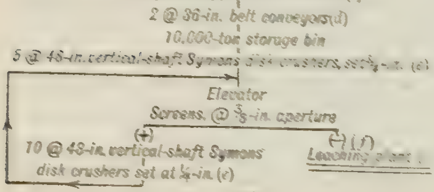

FIG. 5.—New Cornelia Copper Co.

a, Capacity, 35 to 37 tons each. Dumped one at a time directly into crusher hopper. *b*, Capacity of this crusher with head and concaves set for 9-in. discharge was too great (500 tons per hr.) for the gyratories following, hence lower ring of mantle and concaves was made thicker so that the discharge size was reduced to 6-in. and capacity became 400 to 450 tons per hr. *c*, Originally set for 4-in. discharge and "flooded" at 500 tons per hr. (125 tons each) of − 9-in. product of primary breaker. Capacity to −3-in. on −6-in. material from primary breaker is in excess of 112 tons per hr. *d*, Large

and powerful magnets are suspended over each belt and magnet head pulleys are used. The latter alone would not remove all tramp iron. *e*, Coarse crusher has 4-in. annular grinding surface on upper disk; lower, 6-in. Repairs low on coarse disk but high on fine disks. Capacities are 100 tons and 50 tons each per hr., respectively. One 75-hp. induction motor on each machine. *f*, Average screen test, per cent: +3-mesh, 26.3; +4, 16.6; +6, 12.8; +8, 9.1; +10, 7.0; +14, 5.0; +20, 4.2; −20-mesh, 19.0. *g*, Fine dust caused serious trouble. Wetting down in cars allayed slightly, but dust-collecting system had to be added. *h*, See Sec. 15, Fig. 4.

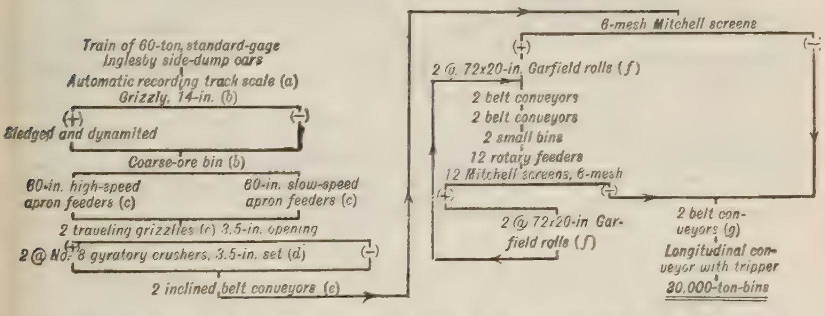
Nevada Consolidated Copper Co., McGill, Nev. Fig. 6. *(123 P 326.)* Steam-shovel mine, ore very soft with considerable clayey material. 13,000 tons per day crushed from steam-shovel size to 6-mesh.

Summary. Receiving bin. Sledging to 14-in.; gyratory, 14- to 3.5-in.; two sets of rolls in series from 3.5- to 0.12-in. Circuit closed on final rolls by means of vibrating screens. All transport and elevation by belt conveyors.

In this flow-sheet the usual arrangement following steam-shovel mining is departed from, a coarse-ore bin precedes the initial crusher and one breaker step only precedes the intermediate crushing. The reasons are: (1) the ore is very soft, breaks relatively small at the mine, and requires but little sledging and mud-capping on the grizzlies to reduce it to pass a 14-in. opening; (2) yard space for storage and switching ahead of the crusher was more expensive to build than a bin; (3) a small amount of hand work in preliminary breaking saved the cost of a large primary crusher.

The reduction made in two steps by the rolls is unusually large. Taking the maximum safe reduction in the first rolls (30° nip angle) would set them at 0.9 in., which leaves a reduction ratio of 7.5 : 1 for the fine rolls. Such work as this at the high capacities maintained would be possible only with very soft ore.

Cost in 1921 was $0.053 per ton.



a, Streeter-Amet. Each car weighed automatically at train rate of 3 miles per hr. Permanent stamped record automatically kept. *b*, Single track on top of a bin 288 ft. long, 29 ft. wide and 14 ft. deep. Horizontal grizzly each side of track, 70-lb. rail, base up. 2-in. compressed-air pipes ending on hopper bottom about 3 ft. from gates aid discharge greatly. *c*, 24 feeders, 8 ft. 9 in. long, set under hoppers spaced along longitudinal center line. All but two center feeders run toward transverse center line, two center feeders run toward ends. The two feeders (oppositely directed) in each half of the bin nearest transverse center line are high speed (about 5 ft. per min.) and discharge onto 60-in. / 118-ft. transverse traveling-belt grizzlies that feed the two gyratory crushers. All other feeders on each side feed onto a 60-in. pan conveyor, thence to the above-mentioned traveling grizzlies. Speed of these feeders is 2.5 ft. per min. *d*, 100-hp. motor, direct-connected to pinion shaft. *e*, 42 in. wide, 120 ft. long; slope, +19° 20′; speed, 250 ft. per min. *f*, Both drive pulleys same side, outboard bearing on fixed roll. 150-hp. motor to each set of rolls. *g*, 42 in. wide, 270 ft. long; slope, +16°; 275 ft. per min.

Fig. 6.—Nevada Consolidated Copper Co., coarse-crushing plant.

Motors. Total hp. @ 860. Every machine except feeders has an individual motor.

Conveyors. All are 42 in. wide; belts, 8-ply with 1/8-in. rubber cover; ball-bearing troughing idlers and Hyatt roller-bearing return idlers.

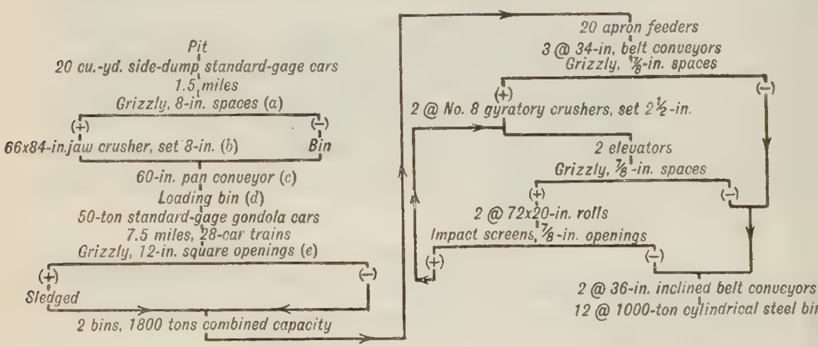
Chutes. All made of sheet steel lined with cast iron or boiler plate.

Chino Cons. Copper Co., Santa Rita, N. M. Fig. 7. (*116 J 1120; 117 J 13.*)
Crushing from steam-shovel size to ⅞-in. at the rate of 12,000 tons per 24 hr. For layout at mine see Fig. 8.

Summary. No receiving bin. Jaw crusher, 60- to 8-in.; gyratory, 8- to 2.5-in.; rolls, 2.5- to 0.88-in. Circuit closed on final rolls by means of impact screens. Bucket elevators used for −2.5-in. material.

This plant is remarkable only in the fact that the initial breaker and secondary breaker are separated by several miles of rail travel. The jaw crusher is the proper initial crusher for the relatively small tonnage of coarse material. Compare with the Utah plants treating a much larger tonnage of similarly sized though softer ore. The use of the bucket elevator for −2.5-in. material marks the age of the plant; without question conveyors would be used for this service in case of rebuilding.

Cost of initial crushing (1924) was $0.0125 per ton.



a, I-beams with manganese-steel caps. *b,* 48 × 60-in. was too light. Now in reserve. Weight, 475,000 lb. Throw at throat, 3¼ in. 80 r.p.m. *c,* Incline, +15°. *d,* 40 ft. long, 14½ ft. wide, 23 ft. high; 567 tons capacity. 6 chutes each side. 50-ton car loaded in 15 min. Louvres over gates. *e,* 60-lb. rail grid under track, over bins.

FIG. 7.—Chino Consolidated Copper Co.

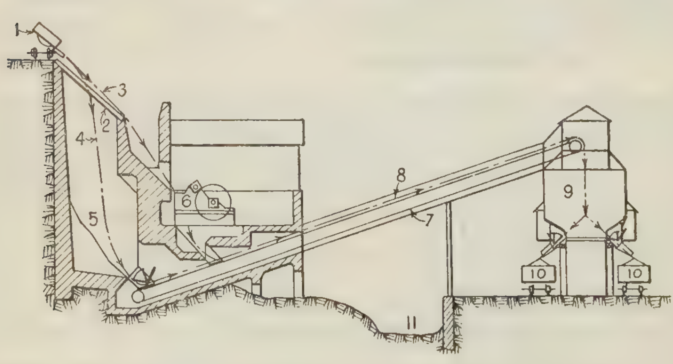


FIG. 8.—Lay-out of coarse-crushing and loading plant, Chino Copper Co.

1. Dump-car train from steam shovel. *2.* Grizzly with 8-in. openings. *3.* Oversize. *4.* Undersize. *5.* Fine-ore bins, 1500-ton capacity. *6.* 84 × 66-in. jaw crusher, 80 r.p.m. *7.* 2 @ 5-ft. steel pan conveyors, 60 ft. per min. *8.* −8-in. *9.* 1450-ton loading bins. *10.* 50-ton cars. *11.* Creek bed.

4. Underground mines

Plants characterized by the use of one breaker only, preceded by a coarse-ore bin.

Ohio Copper Co., Lark, Utah. Fig. 9. *(99 J 749.)*

Crushing from 14-in. to −⅜-in. at 125 tons per hr., one-shift crushing.

Summary. Receiving bin. Jaw crusher, 14- to 2-in.; rolls, 2- to 0.55-in.; rolls, 0.55- to 0.19-in. Circuit closed on final rolls by means of stationary screen. Conveyor and bucket-elevator transport.

This plant is typical of good reduction practice for relatively low tonnages, using a jaw crusher for primary breaking, a pan conveyor to feed the crusher, and removal of fines ahead of the crusher. A belt conveyor in place of the belt-bucket elevator would have cost more for construction, but would easily pay for itself in smoother and more continuous operation. Vibrating screens would undoubtedly replace the stationary screens in a present-day design.

a, Set on slope to elevate from bin to crusher. 15-hp. motor for conveyor and two feeders. ***b,*** Cast-steel T-shape bars; top tapers from 2½ in. at head end to 1½ in. at lower end, thus making openings 1 in. wide at the upper end and 2 in. wide at the lower end of the grizzly. This prevents clogging. ***c,*** Blake type. 150-hp. motor drives this and coarse roll. ***d,*** 70 r.p.m. (See note *c*.) ***e,*** 75-ft. lift, 410 ft. per min. 60-in. head pulley, 42-in. boot pulley. Large concrete pit with broad stairs. Lower part of housing counterweighted to swing away easily. 12-ply belt. 2 rows 9 × 9 × 18-in. buckets staggered 30 in. apart. 3 × 6-in. knocking timbers suspended over the head pulley to jar buckets and loosen sticky ore. 50-hp. motor. ***f,*** Set at 45°. Heavy wire cloth with ⅜ × 1-in. openings. Easily turned end-for-end or over. Efficient except with damp, sticky ore. ***g,*** 70 r.p.m. 75-hp. motor on each. ***h,*** Roll shells 6 in. thick; in two sections, one 10 in. and the other 14 in. wide. Shrunk on. Heat from dry crushing loosens shells unless carefully shrunk. ***i,*** 10-hp. motor.

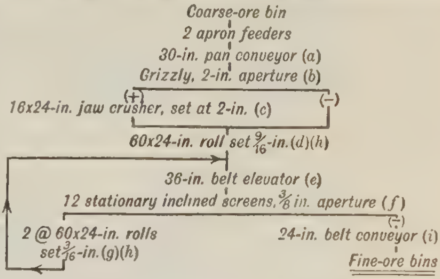

FIG. 9.—Ohio Copper Co., coarse-crushing plant.

United Verde Copper Co., Hopewell, Ariz. Fig. 10. *(104 J 117.)*

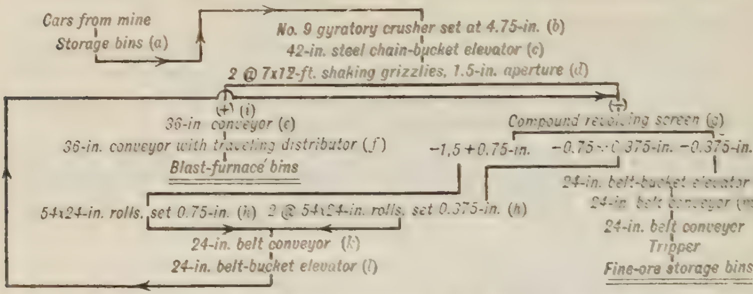
Crushing from 18-in. to −⅜-in. at 400 to 450 tons per hr.

Summary. Receiving bin. One initial gyratory crusher, 18- to 4.75-in.; +1.5-in. lumps not further crushed; rolls, 1.5- to 0.75-in.; rolls, 0.75- to 0.375-in. Circuit closed on final rolls with revolving screens. Conveyor and bucket-elevator transport.

This plant would probably have one or more gyratory crushers to take the oversize of the shaking grizzlies were it not for the fact that this coarse material is wanted for the blast furnaces. The flow-sheet would then become the two-breaker type, or, by making a larger reduction in the primary breaker and using either larger rolls, disk crushers or reduction gyratories for the second machines, the present type of flow-sheet could be preserved.

The secondary crushing is directly comparable with that at NEW CORNELIA (p. 233), eliminating the question of desirability of a granular product at the latter plant. At Hopewell three 54 × 24-in. rolls are used to crush 300 tons per hr. from −1.5-in. to −⅜-in., while at NEW CORNELIA fifteen 48-in. disks crush 425 (aver.) tons per hr. from −3-in. to −⅜-in. Ordinary smooth-faced rolls could not be used to break −3-in. feed to −0.75-in., as is done by the coarse-crushing disks at NEW CORNELIA, on account of nip-angle limitations. It would require 100-in. (diam.) rolls to make this reduction and 78-in. is the largest made (1925). A roll plant for the NEW CORNELIA tonnage, based on Hopewell practice, would require one pair of 78 × 20-in. rolls from −3-in. to −1.5-in., one pair of 60 × 24-in. from −1.5- to −0.75-in., and 3 pairs of 54 × 24-in. rolls to −⅜-in. This is 5 rolls against

15 disks, with a marked advantage for the rolls in first cost and operating expense. See also the comment on the Clarkdale plant of United Verde.



a. One 2-compartment bin, 3600-ton capacity discharged by air-operated slide gates and one 6800-ton auxiliary bin discharging to a 54-in. shuttle belt conveyor with 18 (diam.) × 58-in. 16-section 16-pole magnetic head pulley, thence to a 42-in. pan conveyor, lined with 4-in. maple blocks and running at 40 ft. per min. delivering to crusher chute. Motors: one 5-hp. on shuttle; one 50-hp. on pan conveyor. *b.* 150-hp. slip-ring induction motor. *c.* 68-ft. lift, 45 ft. per min. 75-hp. slip-ring motor. *d.* 11½° slope, 1⅝-in. eccentric, 220 strokes per min., the two driven by a 75-hp. slip-ring motor. Capacity of each grizzly, 400 tons per hr. *e.* 300 ft. per min., 25-hp. induction motor. *f.* 15-hp. motor. *g.* Inside screen, 5 × 18-ft., 0.75-in. holes; outside 80-in. × 15-ft., 0.375-in. holes. Both screening surfaces made of manganese-steel quadrantal segments. *h.* Anaconda type, 1040 ft. per min. peripheral speed, 150-hp. motor. *i.* Amounts to about 30 per cent. of total feed. *j.* 26-in. belt, 250 ft. per min. *k.* 15-hp. motor. *l.* 35-hp. induction motor. *m.* 300 ft. per min. Normal capacity, 200 tons per hr.; possible overload capacity, 150 per cent. *n,* This plant was later superseded by the Clarkdale plant.

Fig. 10.—United Verde Copper Co., Hopewell plant (*n*).

United Verde Copper Co., Clarkdale, Ariz. Fig. 11. (*112 J 833*.)

Crushing from about 18-in. to −3-in. and −¼-in. at 500 tons per hr. For arrangement of machines, see Fig. 12.

Summary. Receiving bin. Four initial jaw crushers, 24- to 3-in.; disk crushers, 3- to 0.75-in.; rolls, 0.75- to 0.25-in. Circuit closed on final rolls by means of screens. Conveyor for coarse and bucket elevator for −0.75-in. material.

This plant is of particular interest when compared with the Hopewell plant of the same company, which it replaces. Four initial crushers of the jaw type replace one gyratory. This increases both first cost and operating cost, when operations are at full capacity, but permits more economical low-capacity operation. The jaw-type crusher is better fitted to handle the clayey ore than the gyratory. Disk crushers replace rolls for intermediate work. This is an economy both in first cost and power cost for the relatively small unit capacities planned and is an example of the use of the disk in the position to which it is ideally suited, *i.e.*, taking relatively coarse feed at a relatively low rate (as compared with big rolls) with less metal and less installed power required per ton of daily capacity. Fine crushing (to 0.25-in.) is done in rolls, which is undoubtedly better practice from the crushing standpoint alone than to use disks. Conveyors have replaced the chain-bucket elevator for handling crusher product but bucket elevators are retained for −0.75-in. material. Storage capacity has been largely and cheaply increased by the use of the stock pile.

Motors. All over 50-hp. are 2200-volt, those under are 440-volt. All motors have push-button control. Remote and multiple push-buttons are used on crushers and long conveyors. All conveyors and feeders on a given ore stream can be stopped by a main button. An electrical interlock controls starting and prevents any piling up of material. Power consumption, 3 kw.-hr. per ton.

Labor. 35 to 40 men; cost about $0.05 per ton.

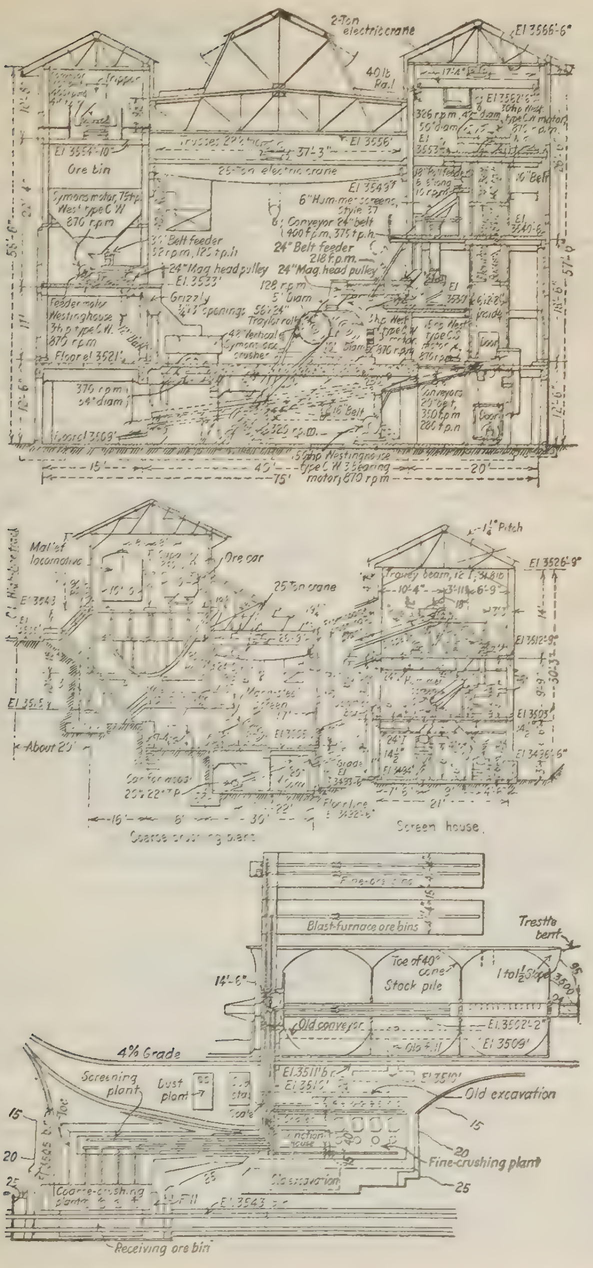


FIG. 12.—Clarkdale crushing plant, United Verde Copper Co.

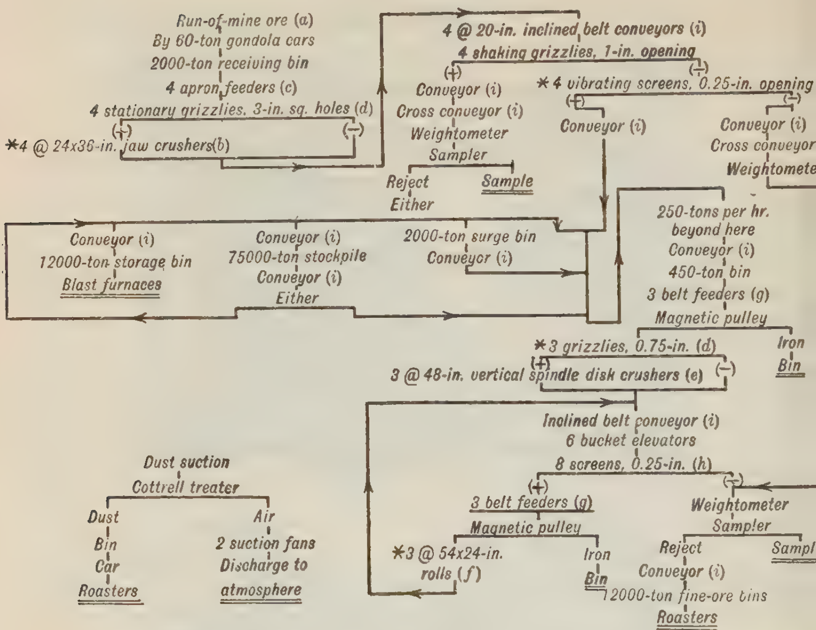


* Connects with dust-collecting system. *a,* Includes hard, massive sulphide from underground workings and both silicious ore and soft clayey material from steam-shovel pits, the hard preponderating. *b,* Each driven by a 125-hp. motor through short-center belts with tighteners. *c,* Driven by individual variable-speed motors with speed reducers. *d,* Manganese steel. *e,* Foundations for a fourth in place; 75-hp. motors for each. *f,* Foundations for a fourth in place; 150-hp. motors for each. Open belts provided with tighteners. *g,* Driven by individual variable-speed motors with speed reducers. Magnetic head pulleys. *h,* 4 Mitchell and 4 Hummer. *i,* Sizes, 20-, 24- and 30-in.; speeds, 250 to 380 ft. per min, depending upon width and capacity. Wide belts are used for coarse material. Short belts are chain-driven from gear speed reducers, intermediate lengths are direct-geared, the long inclined conveyors have tandem drives. Inclines limited to 19°. Conveyors following crushing machines are fed over grizzlies in order to put fines on belt first.

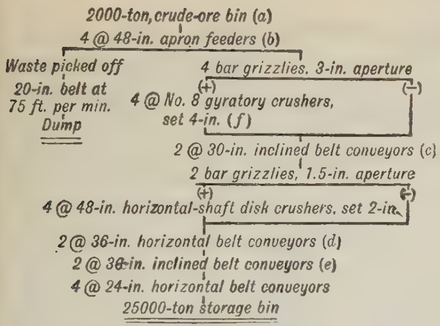
FIG. 11.—United Verde Copper Co., Clarkdale plant.

Inspiration Cons. Cop. Co., Miami, Ariz. Fig. 13. (*55 A 707.*)

Crushing medium-hard granitic porphyry and schist from −12-in. to −2-in. at 1000 tons per hr. 2-shift operation. Arrangement of machines is shown in Fig. 14.

Summary. Receiving bin. Four initial gyratory crushers from 12- to 4-in.; disk crushers from 4- to 2-in. Open circuit. All-conveyor transport.

This plant shows a smaller first cost for crushing machinery and a greater tonnage crushed per unit of installed power than any of the other plants discussed. (See Table 2.) These low-cost figures are due to the fine feed and coarse product and to the fact that the circuit is not closed. On the other hand, labor cost is relatively high due to the fact that four primary crushers require four attendants to pick the feed. The plant has the great advantage that it is built in four substantially independent units so that capacity may be reduced without lowering the efficiency, and 24-hr. operation is possible with only slight loss of capacity for repairs. Floor space is 1.3 sq. ft. per ton of daily capacity. Actual power consumption is about 0.33 kw.-hr. per ton crushed.



a, Steel, double-hopper bottom. *b*, 25 ft. 6 in. long, 7 ft. per min. 20-in. belt conveyors at 7 ft. per min. placed underneath catch drip and spill and deliver to grizzly-undersize chute. *c*, Magnetic head pulleys. *d*, Short cross conveyors. *e*, 300 ft. long, 350 ft. per min. *f*, Each unit of the 4 shown is driven by one 200-hp. motor, placed in dust-proof rooms.

a But note that about 130 tons is rejected at − 4.75 + 1.5-in. *b* Estimate based on roll crushing all feed to pass ⅜-in. *c* Estimated. *d* Estimated on basis of 500 tons per hour down to ¼-in. Present capacity is 500 tons per hour through the initial crushers and 250 tons beyond this.

This, although an underground mine, can handle lumps into the mill-ore trains of a size approximating those from steam-shovel mines. The coarse-crushing flow-sheet is, therefore, of the steam-shovel-mine type with 2 breakers in series ahead of the intermediate crushers. The use of a bin for + 10-in. material ahead of the initial crushers is unusual and fraught with danger of clogging in the discharge gates. The breakers are installed on shelves on the side of a great hole cut in solid rock and material flows by gravity from the tipples to the bin storing the − 2½-in. size Reduction in final rolls is larger than is customary. The use of automatic hoists is unique. Several of the men intimately and responsibly connected with their operation vouch (*PC*) for their smooth and satisfactory operation, after the troubles incident to starting were overcome. They have the advantage over belt conveyors of making a very compact plant, particularly where large vertical lift is necessary; and with the mechanical difficulties incident to a new type of machine overcome, should be much superior to bucket elevators.

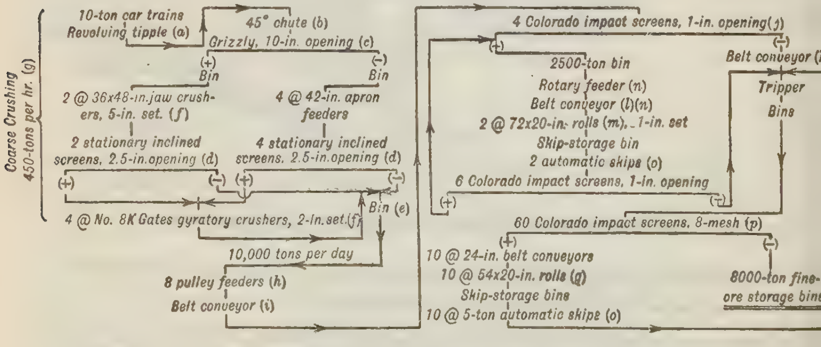

FIG. 15.—Coarse-crushing plant of Alaska Gastineau Mining Co.

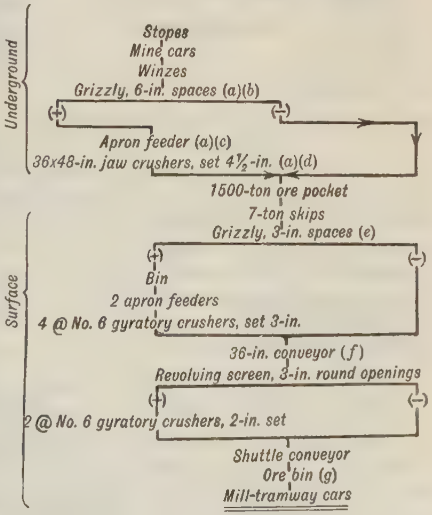
a, Capacity, 4 cars. 2 tipples operated by 50-hp. motor. Friction clutch between motor countershaft and tipple mechanism, band brake on tipple. *b*, Lined with worn-out roll shells, 1 in. thick, straightened at red heat by steam hammer. Cheaper than boiler

plate and has longer life. *c,* 8-in. steel I-beams with manganese-steel caps. Several beams failed by bending after 6,000,000 tons, but caps were still good. *d,* 3 ft. (wide) × 14 ft.; 45° slope; crimped-wire cloth. *e,* Underground, 8000 tons cap. *f,* One jaw and two gyratory crushers with grizzlies and screens constitute a separate unit. Crushers are clutch-driven from a countershaft which, in turn, is driven by a 200-hp. motor. *g,* Crew: 1 crusher man, 1 feeder man, 1 oiler each shift; 1 repair man and helper on day shift; rigger crew as necessary for changing jaw plates, mantles and concaves. *h,* 36 × 36-in. Different feeders operated at different times to overcome size segregation in bin. *i,* 42-in., 1216 ft. long, 8-ply, slight down slope. *j,* All steel, extra heavy. *k,* 42-in.; 8-ply belt. *l,* 36-in. *m,* 80 r.p.m. 300-hp. motor for rolls, conveyor and feeder. *n,* Driven from roll shaft. Capacity: oversize from daily mill feed of 12,000 tons per 24 hr. *o,* Each 5-ton capacity. 75- to 135-hp. Westinghouse hoist motor operates one hoist drum for 2 skips in balance. Air cylinder operates skip-loading gate through 3-way valve on a shaft actuated by the descending skip. Loading time (11 sec.) determined by an oil dash pot that throws the motor switch. Lift, 100 ft. Maintenance cost $0.009 per ton milled. *p,* 0.032-in. aperture (some are 9-mesh, 0.028-in. aperture). Steel-wire cloth. 600 vibrations per min. Manganese-steel cams and tappets. *q,* Set to grind to 10-mesh. Roll feed sprayed to lay dust. One 300-hp. motor direct-connected to a line shaft for each two sets of rolls. Capacity, 1100 tons per 24 hr. from 1-in. to 10-mesh.

5. Underground crushing plants

Underground crushing plants are used to lessen the difficulty of loading large lumps into the hoisting skips, and thereby decrease shaft delays. They are to be considered only when the character of the ore and the method of mining produce large lumps at the stope chutes and skip-hoisting is employed. Under such circumstances placing the primary breaker underground may result in sufficient time and labor saving in skip-loading to counterbalance the disadvantages, of which the principal ones are the high cost of installation; separation of the initial crusher from those following, with consequent increase in labor cost and superintendence; and dust production. Where ore haulage takes place on several levels, the output is usually sent to one crusher by long steeply inclined chutes through which ore travels by gravity. At HOMESTAKE (see below) the working levels extend 1500 to 1800 ft. vertically, necessitating 3 crusher levels, to save excessively long ore passes and excessive loss of elevation of the ore. The disadvantages of this arrangement are the multiplication of initial crushers and their wide separation, with the attendant multiplication of labor and difficulty of supervision. At the Lebanon plant



a, One each at 800-ft., 1400-ft. and 2000-ft. level. (See Fig. 17.) *b,* Made of 6-in. steel shafting on cast-iron supports. *c,* 5 ft. wide × 5 ft. 3 in. long. *d,* Frame, semi-steel, cast in halves which are held together by keys and heavy steel bands. Motor, 125-hp., 720 r.p.m., 2200-volt, slip-ring type. Lenix drive. Crusher capacity, about 200 tons per hr. *e,* Hard cast-iron wedge bars, 6 in. deep, 1½ in. wide at top and 1 in. at bottom. *f,* Magnetic head pulley. *g,* 100 ft. long, 20 ft. wide, 60 ft. high.

Homestake Mining Co., Lead, S. D. Fig. 16. (*122 P 539.*)

Ore: Hard quartz and slate.

Summary. Receiving bin (ore pass). Jaw crusher from 30- to 4.5-in.; gyratory crushers from 6- to 3-in.; gyratory crushers from 3- to 2-in. Open circuit. Conveyor and skip transport.

6. Stage crushing

It is an axiom of modern crushing practice to perform the reduction in size from mill feed to final tailing in stages, irrespective of the demand for stage crushing imposed by metallurgical requirements. Experience has taught that this makes for economy, both in power consumption and maintenance. Argall recommended a maximum reduction ratio of 4 to 1 for breakers, *e.g.*, 8-in. to 2-in. maximum size, and condemned the use of stamps crushing from 2-in. to 0.02-in. (100 : 1) as very inefficient. He pointed out that certain machines are best adapted to work within a given range of size reduction, *e.g.*, breakers down to 2-in. and rolls for the next step but not for coarser material. Barring occasional exceptions, such as the greater efficiency of Chilean mills on ¾-in. feed than on ¼-in. feed or finer and of tube mills on ¼-in. feed as compared to 10- or 20-mesh, the smaller the reduction ratio down to, say, 2 : 1, the greater the efficiency of the machines. In coarse crushing plants this fact has been long recognized; reduction ratios in a given

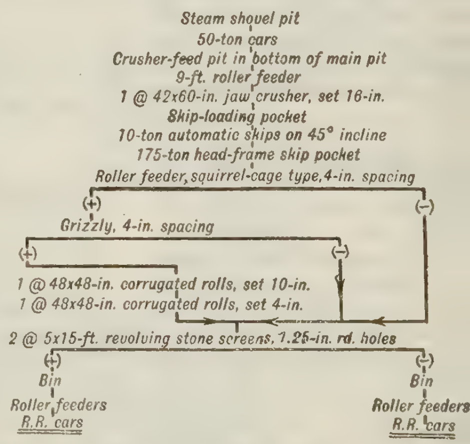

Fig. 18.—Coarse-crushing plant, Cornwall mine.

machine rarely exceed 4 : 1, except occasionally in case of the primary breaker, and are generally less than 3 : 1.

Closing the circuit on a coarse crusher results in making it work through too great a range of initial sizes and imposes an additional task that could

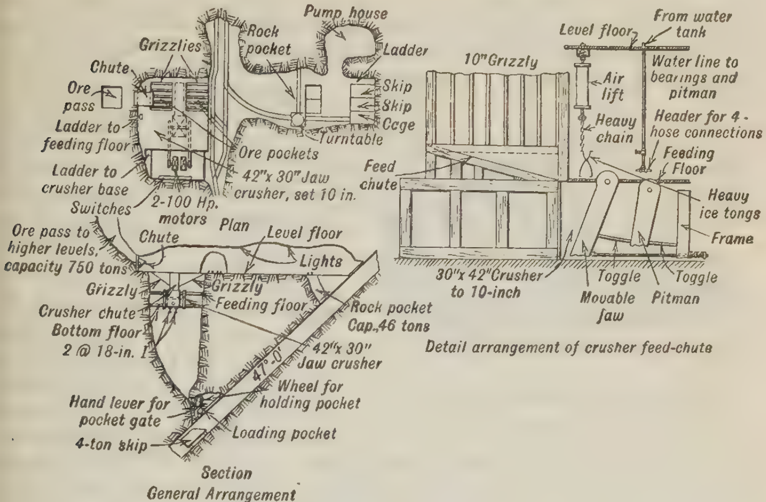

Fig. 19.—Underground crushing station at Creighton mine.

be much better performed by a crusher adapted particularly to breaking the material returned, hence coarse-crushing circuits are closed only when necessary and then only with respect to the final crusher. This requires more crushers, but the crushers work more efficiently, screens and transporting equipment are reduced in number and amount, and overall economy is increased.

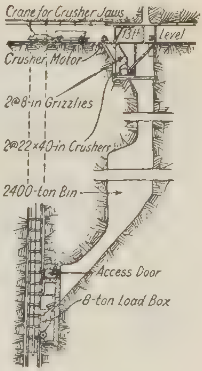

Fig. 20.—Crushing station on 13th level, Crown Mines, Ltd.

Sending natural feed to a crusher results in giving it material that it is not adapted to crush and increases wear and power consumption, therefore undersize is usually screened out ahead of crushers except where this would cause too great complexity of design.

When rolls are used in fine-intermediate crushing, say, to produce 10-mesh roughing-table feed prior to flotation, an apparent exception to the rules against large reduction ratio and closed circuit is found in the practice of feeding material as coarse as 1-in., setting the roll faces close and building up a large return circuit with a screen. But this is done in order to establish a condition of choke-crushing, otherwise impossible to attain with any degree of economy, and, as a matter of fact, such rolls are to be considered as grinders, in which larger reduction ratios are desirable than in coarse and intermediate crushing. Stamps were for many years looked upon as fine

grinders, and experience seemed to show greater economy in crushing throug say, 16-to 20-mesh screen, if the feed was 1- to 2-in. maximum size than if it w

Table 8. Classification of common crushing machines

Machine	Maximum feed, inches	Minimum product (a)
Jaw crusher	66b	2-in.(c)
Gyratory crusher	52d	2-in.(c)
Reduction gyratory	8	$\frac{1}{4}$-in.(c)
Disk	$4\frac{1}{2}$	$\frac{3}{8}$-in.(c)
Rolls (smooth-face)	3–4	10-mesh
Stamps	$1\frac{1}{2}$–$2\frac{1}{2}$	$\frac{1}{2}$-in. to 10-mesh
Rod mills	1	10- to 35-mesh
Ball mills	$\frac{3}{4}$–3	65- to 200-mesh
Pebble mills	$\frac{1}{2}$	65- to 300-mesh

a Meaning the size of the largest particle in the product when the particular type of machine is set to crush as small as is economically desirable. Where a range of sizes is indicated the machine is suited to the production of any maximum size within the range. *b* In a 66 × 84-in. machine. An 84 × 120-in. machine is advertised by one maker but none has been built. *c* This size does not, of course, correspond to the feed size in the preceding column, but to a smaller machine. Finer crushing in this machine may be justified on the ground of simplicity or cheapness, in small plants. *d* This is the minimum dimension of the largest particle that a No. 27 machine (54-in. gape) will take. Machines of 72-in. gape are advertised by one maker but none has been built.

$\frac{1}{2}$- to $\frac{3}{4}$-in. or finer. B with the introduction of tu mills it was quickly an clearly demonstrated th the two machines in seri were more economical in pr ducing fine material th stamps alone (and, until th work of Davis, *et al.* (21 988; see also Sec. 4, Art. than either alone) so th stamps were relegated to th position of fine-intermedia crushers, breaking from 2- 3-in. maximum to $\frac{1}{2}$- or in. and the balance of t crushing to 0.01-in. and fin is done in tube mills. Dav (see Sec. 4, Art. 8) has de nitely proved experimental the advantage of stage crus ing in ball milling. A simil conclusion has been reach at every plant where caref comparison of 1-stage *vs.* mu tiple-stage reduction from or 3-in. maximum to flotation feed (0.2-mm.) or finer has been made. Tab 8 gives the range of sizes through which the different common crushi machines are used.

CRUSHING MACHINES

Classification of crushers. Coarse crushers are those that take ru of-mine ore and discharge material much coarser than ordinary concentrati size. Fine crushers or grinders discharge products crushed to concentra ing size, usually 2-mm. or under. Intermediate crushers are those install between the coarse and fine crushers in a mill. This latter designation based rather upon the place of the machine in the mill flow-sheet than up its characteristics as a crusher.

Coarse crushers are built large enough to take any rock that can handled by a steam shovel and the term is used also to describe crushing m chines, the feed to which is not, in general, less than 3-in. They are of fo general types, (a) jaw crushers, (b) gyratory crushers, (c) disk crushers, a (d) rolls.

7. Jaw crushers

Jaw crushers consist essentially of two crushing surfaces set nearly v tically, one fixed, the other movable and caused to alternately approa and recede from the fixed surface. The best known types are the Bla with movable jaw pivoted at top, and the Dodge with movable jaw pivo at the bottom. Mill crushers are almost without exception of the Blake ty

Blake breaker (Fig. 21) consists of a main frame (*a*) carrying a fixed jaw (*b*) and a movable jaw (*c*), the latter pivoted at the top on the swing-jaw shaft (*d*). The movable jaw is caused to oscillate by the action of toggles (*e*) and pitman (*f*) actuated by the eccentric (*g*) through the medium of pulleys (*h*) mounted on the drive shaft. One pulley only is used on small crushers. The movable jaw is held up against the toggles by tension rod (*j*) and spring (*k*). The rear toggle is seated against adjusting block (*l*). The horizontal position of the rear toggle seat is changed by raising or lowering the block (*m*) by means of the bolt shown, thus determining the distance between the fixed and movable jaws. The throw of the swing jaw may be varied slightly by raising or lowering block (*l*). Heavy fly-wheels (*n*) are mounted on the drive shaft for the purpose of lessening the intermittent character of the load on the prime mover. A jaw crusher breaks rock only during that half of each revolution in which the movable jaw is approaching the fixed jaw; during the other half revolution the only work done is that in overcoming friction. Without fly-wheels a driving belt flaps badly and there is a tendency for the prime mover to run away on the unloaded half of the revolution while it is subject to an enormous power draft on the loaded half. Fly-wheels average the load by storing energy during the unloaded half of the revolution and returning it during the loaded half. Table 4 presents essential data concerning Blake crushers, taken from manufacturers' catalogs. For most sizes the figures given have been checked against operating data and found to be conservative.

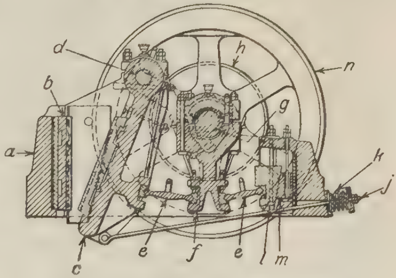

Fig. 21.—Blake jaw crusher.

Main frame must withstand constant vibration and heavy shock loads which produce tensile stresses around the mouth and near the base and compression under the main bearings. There is considerable racking strain due to uneven loading of the jaws. In small crushers (up to 15 × 30-in.) the frame is usually made in one piece, of cast iron (tensile strength, 20,000 to 30,000), cast semi-steel (28,000 to 35,000), or cast steel (60,000 to 75,000). In large crushers a cast-steel frame, thoroughly annealed, is made in four pieces, two ends and two sides. These pieces are fitted together with carefully machined tongue-and-groove joints and secured by heavy bolts and tie-rods of high-carbon steel (100,000 to 150,000 tensile strength) put in hot. Castings are heavily ribbed to give strength, while allowing considerable saving in weight. The principal tensile stresses are longitudinal and the longitudinal tie-rods are made sufficiently heavy to withstand these stresses without aid from the sides of the frame. Bearings for the pitman and swing-jaw shafts are best cast integral with the frame to aid in shaft alignment. The sides should be strengthened at these bearings by ribs, and in addition, by cross tie-rods or by collars set in grooves or screwed onto the shafts. In the largest crushers the side pieces are sometimes made in two parts, split horizontally and fastened together with bolts of alloy steel. Cast-iron and semi-steel one-piece frames are sometimes reinforced with steel, shrunk on around the jaw openings and base. The Calumet and Hecla-type crusher has a one-piece ribbed frame reinforced by 3 @ 5-in. longitudinal bolts each side, 3 @ 4-in. bolts across the front end and 2 @ 4-in. bolts across the rear end. By this expedient the weight of a 24 × 48-in. crusher is kept down to 80,000 lb.

Swing jaw is subjected almost entirely to bending loads. It is made of the same material as the frame, and, in large crushers, is similarly ribbed. It is shrunk or otherwise rigidly fastened to the swing-jaw shaft in order to bring the movement into bearings that are readily accessible for lubrication. The face of the jaw is machined to give an even bearing for the jaw plates. Some manufacturers make removable toe plates for the swing jaw so

that they can be replaced when worn, this being the only part of the swing jaw that is subjected to excessive wear.

Pitman stresses are almost wholly tensile. In all but the smallest crushers the pitman is made of cast steel, thoroughly annealed. Every attempt is made to make it of the least weight consonant with the required strength. This end is ordinarily attained by the use of a heavy ribbed casting of box section, but one manufacturer makes a cast-steel cap and a toggle support separately and joins them together with wrought-steel tension rods. Several manufacturers of large crushers support the pitman on a nest of springs resting on a heavy cross-head on the frame. This reduces friction and consequent heating of the bearings, thereby saving power and lubricants and lessening or eliminating the necessity for pitman cooling. At CALUMET AND HECLA (*100 J 11*) substitution of a spring-supported pitman for the old style reduced the power consumption on a given crusher from 29 to 16 hp. Bolts holding down the pitman cap should have fine threads to aid adjustment.

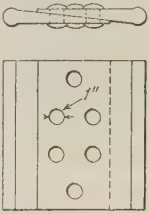

FIG. 22.—Split toggle for jaw crusher.

Toggles are subjected to compression only. The ends of the toggles, rolling or sliding in the toggle seats, are difficult, if not impossible to properly lubricate, and since substantially the full crushing force is concentrated here they must be specially hardened to resist wear. Toggles are made of cast iron in small, cheap crushers. Small crushers of better grade have cast semi-steel or steel toggles with chilled ends. Large crushers are fitted with cast-steel toggles with chilled ends or with toggles made of alloy steels. In many crushers the rear toggle is made the BREAKING POINT to relieve strain when steel gets into the jaws. In some cases this is accomplished by splitting the toggle along a diagonal plane as in Fig. 22 and riveting together with just enough metal to withstand all normal strains, but insufficient to stand an excessive load. At TALISMAN MINE, N. Z., six 1-in. rivets in a 16 × 10-in. crusher sheared with a hammer head. At LYELL COMSTOCK, Mt. Lyell, twelve 1-in. rivets were used in a 12 × 20-in. crusher. Some manufacturers make the rear toggle itself of such light section that it fails when excessive load is applied.

Life of toggles varies from 90 days to several years, the majority less than a year. One mill reports the use of toggles with replaceable ends, and change of ends necessary after 4 to 6 months.

Toggle seats are subjected to the same wear as toggle ends, but are less easily replaced and hence greater care is taken to insure long life. In small crushers they are made of hard, high-carbon steel; in large crushers of manganese or chrome steel. From its properties, a chrome steel containing 1 to 2 per cent. chromium and about 1 per cent. carbon, hardened, should be the best possible material for this service. A rolling toggle, such as illustrated in Fig. 23*a*, with chrome-steel toggle-block and liners should be superior to any form of sliding toggle such as illustrated in Fig. 23*b*.

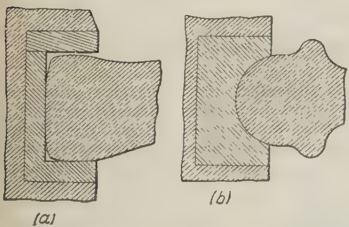

FIG. 23.—Toggles and toggle seats.

Life reported in the mills ranges from 90 days to several years. Manganese-steel blocks on large crushers under fairly heavy load lasted from 1 to 2 years.

Shafts are subjected to enormous bending stresses and should be of large diameter to prevent deflection and consequent heating of bearings, as well as to guard against breakage. In all high-grade crushers they are made of best quality high-carbon steel forgings, heat-treated and tempered, then turned and polished.

Bearings are heavily loaded even when the crusher is running light. They should, therefore, be of large diameter and as long as possible. In one-piece frames the bearings should be cast integral with the frame to aid in proper alignment of shafts. When frames are cast sectional, proper alignment is obtained by the use of ball-and-socket bearings. The pitman-eccentric bearing is water-cooled in all good crushers except those in which the pitman is spring-supported. The pitman-shaft end bearings are often likewise water-cooled in large crushers (30-in. opening and upward). The best quality of hard babbitt is used.

Fly-wheels are subjected to heavy strains by reason of the rapidly and greatly varying load on the crusher and must, therefore, be built especially strong. They are usually made of cast iron or semi-steel. When cast in one piece special precautions must be taken to insure against cooling strains. Some manufacturers cast rim, hub and arms separately

and thus eliminate shrinkage strain One manufacturer keys the fly-wheel to the shaft with compression keys that allow slip with overloading, but this is probably an unnecessary precaution so far as fly-wheel breakage is concerned and insufficient provision as a breaking point to save the crusher bearings in case of entrance of tramp iron. Rims on all large crushers are cored for pockets to allow barring over and are crowned when the fly-wheels are to be used as drive pulleys.

At Calumet and Hecla the end of the shaft is marked with an arrow to show the position of the eccentric and thus make it apparent which way to turn in order to ease off when the crusher is clogged.

Heat treatment of crusher steel is highly important. Harder (*115 J 314*) tested parts of jaw and gyratory crushers and rolls that had failed in service and found in all cases that the tensile and impact strengths, toughness and hardness were markedly increased by simple heat treatment.

Drive of small crushers is by a single pulley carried on an extension of the eccentric shaft or bolted to a fly-wheel. The usual practice is to use two pulleys on crushers with greater than 24-in. width of receiving opening, if drive is from a counter-shaft, but when direct belt drive from a motor is employed, one pulley only is used. At Creighton mines Ont., a 30 × 42-in. crusher is driven by two 100-hp. motors. The principal objection to single-pulley drive is the unbalanced side pull on the bearings. This is not serious, if the

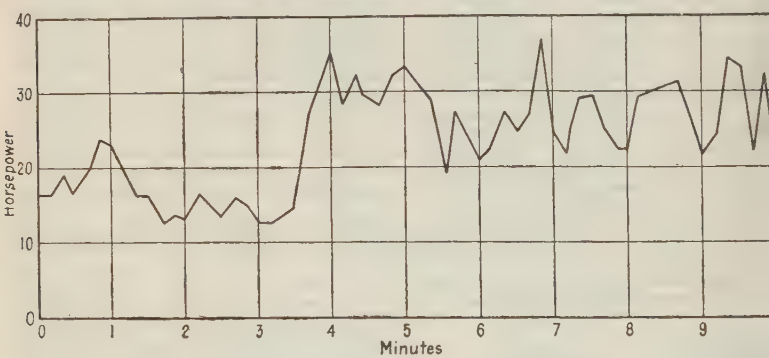

Fig. 24.—Power draft of 18 × 36-in. Blake jaw crusher.

shaft and bearings are properly designed. In some large crushers the fly-wheels are replaced by extra-heavy flanged drive pulleys or rope sheaves, in some cases counter-weighted to balance the pitman. Lenix system is frequently used for driving crushers of all sizes. When two drive pulleys are used, each should be sufficient for independent drive. Pulley dimensions are generally based on transmission of 1 hp. per inch of drive belt traveling at 1000 ft. per min. Installed horsepower is generally well in excess of that actually used, in order to take care of the starting load. One mill reports a 150-hp. motor installed on a 24 × 36-in. crusher drawing 186 hp. at starting and 92 hp. running under regular load. Tests at Witherbee Sherman and Co. mills (Fig. 24) indicate fluctuations from 19 to 3 hp. within a minute in the power draft of an 18 × 36-in. crusher running under full load (185 r.p.m.; 8- to 10-in. max. size of feed; −4-in. product; 102 tons per hr.). Crushers must, therefore, be over-powered, if serious speed reduction and clogging are not to result from peaks in the power draft.

Lubrication of jaw crushers is difficult on account of the great pressures on the bearings and the large amount of dust and grit present. All well-built crushers use forced feed of either grease or oil. Because of the way in which exuding grease forms a collar that excludes dust and grit, most manufacturers use grease fed by means of compression cups with automatic or manual feed. Some crushers are fitted with compression feed to the under side of the pitman-eccentric and pitman-shaft bearings and large grease or oil reservoirs on top for gravity feed. Toggle seats are most difficult to lubricate and that design of toggle and seat is best that minimizes the need for lubrication.

Consumption of lubricant as reported by various mills is shown in Table 10. The enormous differences are apparently due to differences in crusher duty. High consumption of lubricant corresponds to heavily loaded crushers and *vice versa*.

Jaw plates. The principal wear on the crusher comes on these and on the cheek plates. They are, therefore, made replaceable. Further, wear on the jaw plates is uneven and i

order to lessen the amount of metal discarded in the form of worn plates, they are made reversible In the case of large crushers with sectional jaw plates, they are also made interchangeable Thus in a small crusher, when the jaw plates become worn at the throat, where wear is greatest, they are turned end for end and their life is practically doubled. When plates are sectionalized horizontally, two wears are added for each such sectionalizing. When the form of surface corrugation permits, further increase in life of plates is gained by also sectionalizing vertically, when four wears at the throat can be had from each section. In addition to longer life, sectionalizing makes for ease in handling, which is a great advantage in large crushers. Materials used for jaw plates are chilled iron, white iron, high-carbon cast steel, forged steel, manganese and chrome steels. The great majority of plants use manganese-steel plates. This material is particularly fitted for such service on account of the fact that it is tough and that surface abrasion produces rapid and marked surface hardening. One special form of jaw plate is made of forged and rolled chrome-steel bars cast-welded into a back of open-hearth steel and subsequently tempered. This gives a hard chrome-steel crushing surface, while the untempered back is tough and resists cracking. Chilled steel wears unevenly because it is initially uneven in hardness. CALUMET AND HECLA uses chilled cast-iron plates for crushing soft amygdaloid and manganese steel for the hard conglomerate. The main frame and swing jaw are carefully surfaced to give full, even bearing to the jaw plates, or the plates may be backed by zinc or hard babbitt. Plates in small crushers are usually wedged in; those in large crushers are bolted in. One maker places a buffer plate between the wearing plates and frame to take up any wear on frame due to the abrasive action of grit, in case the liner plates loosen and vibrate.

Life of jaw plates varies according to material used and service required. (See Table 10.) Three to six months is an average life for manganese-steel plates in ordinary service. One plant reports 40 days' life for manganese-steel plates in an 18 × 30-in. crusher handling 1500 tons per 24 hr. of hard granitic ore. Another reports two to four years for plates of the same material in a 36 × 42-in. crusher handling 4000 to 5000 tons per 24 hr. of hard slate with some quartzite. The consumption of manganese steel, including waste on rejection, is from 0.01 to 0.06 lb. per ton of rock crushed. The consumption of chilled iron in small crushers ranges from 0.02 to 0.2 lb. per ton and averages about 0.1 lb. per ton. Johnson (*101 J 907*) gives the following comparative figures on chrome and manganese steel in the same service: chrome steel, weight of plates, 921 lb.; cost f.o.b. mill, $96.93; life, 70,206 tons; manganese steel, weight, 740 lb.; cost, $72.62; life, 86,478 tons. It must be remembered that manganese steel, as well as all other metals, varies markedly in grade and wearing qualities. Waterhouse (*38 Aa 107*) cites a set of manganese-steel jaw plates of Sheffield manufacture that served to crush 6100 tons in a small crusher against a life of 4500 tons for local Australian plates of substantially the same manganese content. Del Mar (*40 MEW 687*) recommends 13 per cent. Mn as the best alloy.

The time required to change jaw and cheek plates is from one to three hours for crushers up to 24 × 36-in. One mill using a 36 × 42-in. crusher reports eight hours to make a change of plates.

The crushing surface of jaw plates is made in a variety of forms. For fine crushing and brittle rock, plane surfaces are best; for all-around coarse work, a surface corrugated vertically with 90° ridges as shown in Fig. 25 is best, but in crushing soft, tough rock the ridges are likely to pulverize locally without effecting a break. A waved surface has the advantage of concentrating the breaking load without the disadvantage of local pulverization. It discharges more readily than the corrugated, thus increasing capacity. It is especially suited to tough, slabby rock, like slate. Waved plates are used in several Lake Superior copper mills in preference to corrugated, since they allow mass copper that has caught to be freed by working sideways, which cannot be done with corrugated plates.

FIG. 25.—Corrugated jaw plate.

Cheek plates take wear on the sides of the crushing opening. The materials used are ordinarily the same as for jaw plates. The surfaces are plane. The plates are wedged in in small crushers and bolted through in large. The life of manganese-steel cheek plates is the same or slightly less than that of jaw plates of the same material and metal consumption is usually less than 0.01 lb. per ton crushed. Chilled-iron plates have about one-quarter to one-third the life of manganese-steel.

Adjustments of Blake crushers are, (1) width of discharge opening, (2) THROW, *i.e.*, the distance traveled in each direction by the jaw at each revolution of the drive shaft, and (3) speed.

Width of discharge opening is adjusted by changing the length of the

toggles, changing from worn to new jaw plates, or by a wedge or shim adjustment of the rear toggle seat. Ordinarily sufficient wedge or shim adjustment is provided to compensate for jaw-plate wear and this adjustment is made from time to time as plates are worn down. Change in length of toggles is usually made only when the duty of the crusher changes and a wholly different size of product is desired.

Throw, in Blake crushers, is measured at the throat. It is adjustable in some crushers by a device for raising or lowering the main toggle block and thus changing the angularity of the toggles, but ordinarily this adjustment involves a change in the eccentric and requires a new pitman or, at the least, a new eccentric. Throw ranges from about $\frac{3}{8}$ in. as the minimum in small crushers up to 1 in. minimum in large crushers. The maximum throw is about twice the minimum figures. The principal factor determining the length of throw is the character of rock to be crushed. If the rock is hard and brittle, so that the jaws do not pulverize locally and deformation prior to fracture is not great, the minimum throw may properly be employed. If the rock is of such character that the reverse situation prevails, and there is local pulverization and a tendency for the rock to crack and be deformed under load but not to fall apart, then the maximum throw should be used. Firm quartzitic and acid rocks generally require only the minimum throw. Tough, basic rocks, highly crystalline rocks, slabby rock, and decomposed rocks in general require the greater throws.

Speed can be varied only by change in the speed of the prime mover or by a change in pulley ratios in the power-transmission chain. Change in speed affects capacity and power consumption, but has no marked effect on the size of product. Lake Superior rock-house practice varies the speed according to the hardness of rock crushed (*100 J 55*). At QUINCY, breaking soft amygdaloid, the speed is 140 r.p.m.; at CALUMET AND HECLA, with a feed of hard conglomerate, the crusher is run at 175 r.p.m. and at COPPER RANGE, crushing dense amygdaloid, the speed is 185 r.p.m. Excessive speed causes heating. At MOOSE MOUNTAIN (*99 J 974*) a 24 × 36-in. crusher overheated when run at 250 r.p.m. but gave no trouble when run at 180. There was, however, an accompanying decrease in capacity.

Reduction ratio is the ratio between size of feed and size of product in a crushing operation. The sizes considered are usually maximum sizes, although in some instances consideration of average sizes is more informative. NIP ANGLE in jaw crushers is the angle formed by the jaw faces. Table 5 gives data concerning the nip angle and maximum reduction ratios in Blake crushers estimated from manufacturers' data. The average reduction ratio for crushers of all sizes, with minimum setting, is 8.7; for maximum setting, 5.4. Larger reduction ratios are allowable in the smaller crushers by reason of the fact that the nip angle corresponding to these large ratios is smaller in these crushers. Maximum nip angle corresponding to the above ratios is less than 24°. In the mills the average reduction ratio for 20 crushers ranging from 6 × 20-in. to 66 × 84-in. size was 7.46 (see Table 10); the maximum is 18.6 and the minimum 2.6. The corresponding nip angles range from 18° to 23°, the maximum angle corresponding to the largest crusher. It is to be noted that the above reduction ratios are those of which the crushers are capable according to their size and setting and not, necessarily, those under which they are called on to perform. In general the maximum particle of feed is somewhat less than the gape of the receiving opening and the average size of the feed is much less. The average reduction ratio is, therefore, less in

every case than the figure given. The nip angle increases as the jaw moves forward, hence, if the angle is too large with the jaws open the unfavorable condition is aggravated as the jaw closes.

Table 5. Reduction ratio and nip angle in Blake crushers

Size of crusher, inches	Minimum setting			Intermediate setting			Maximum setting

Average..	......	8.7	....	......	6.6	....	......	5.4	

Capacity of Blake crushers depends primarily upon the character of ore, size of feed, and discharge setting. It is materially affected, also, by the throw, speed, angularity of jaws, and character of surface of the jaw plates. Capacity figures averaged from manufacturers' catalogs are given in Table 4. These figures are based on rock such as limestone, which is easy to crush. On the other hand, they are generally given in terms of a feed none of which will pass through the crusher without breaking, while the ordinary feed to a crusher contains a considerable percentage of material that requires no breaking but passes directly through. Quartz, quartzitic ores, and firm brittle ores generally can be crushed at a rate equal to catalog figures. Tough ores, such as basic silicates, traps and diorites, do not crush so readily. Hersam (*68 A 463*) shows that if the capacity of a given crusher on quartz is taken as 100, the capacity on a granite such as he tested would be 89.5 and on a trap, 83. Materials of low specific gravity such as coal, fibrous materials such as asbestos, and clayey materials, can be crushed only at rates markedly below catalog figures. The effect of variation in density is indicated by Table 6. The column headed "Relative volumes per hour" shows that there is a distinct

Table 6. Effect of density of feed on capacity of jaw crushers. (*After Hersam*)

Material	Sp. gr.	Relative tons per hour	Relative volumes per hour
Coke....................	1.11	100	100
Coal....................	1.91	170	100
Granite..................	2.66	381	159
Stibnite in quartz...........	3.03	436	159
Chalcocite in quartz.........	4.40	641	162
Galena in quartz............	6.15	950	172

trend toward the passage of a larger volume of dense material through the crusher in a given length of time. Sticking of clayey materials may be considerably lessened by allowing a trickle of water to run into the crusher with the feed. This tends to lubricate the crushing faces sufficiently to allow the compressed material to slide forward as the movable jaw recedes and thus to work through the crusher. In crushing slate, which cleaves easily and tends to discharge from the crusher in slabs much larger in one or two dimensions than would be expected from the crusher setting, there may be considerable reduction in capacity, due to the measures that must be taken to prevent such discharge.

At one plant crushing slate discharge of slabs was prevented by attaching prongs at 6-in. intervals to the bottom of the swing jaw, these prongs projecting across the throat and under the fixed jaw plate. The feed to the crusher ranged from pieces that would just enter the 15 × 24-in. receiving opening, to pieces that could pass through without any crushing. The crusher was set for a minimum opening of 1⁵⁄₁₆ in. and had a throw of 1 in. The capacity without prongs was 25 tons per hr. and the product contained about 2 per cent. of slabs that stayed on a 4-in. screen. The capacity with prongs was 20 tons per hr., but there was no slabby material in the product. The average size of the product was not greatly altered.

There is a marked progressive increase in capacity with decrease in reduction ratio. With a crusher having a minimum throat opening of 0.24 in. and a throw of 0.21 in., crushing a uniform granite of various sizes, Hersam reports the results summarized in Table 7.

Table 7. Effect of reduction ratio on capacity of jaw crushers. (*After Hersam*)

Size of feed, inches	Reduction ratio	Relative tons per hour
3 to 4	8.9	100
2 to 3	6.7	170
1 to 2	4.4	182
0.5 to 1	2.2	232
0.125 to 0.5	1.1	419

Capacity increases with increase in speed up to a certain limit although the increase is not a proportionate one. See Table 8.

Increase in nip angle decreases capacity somewhat, as shown by Hersam's tests summarized in Table 9. Note, however, that the effect is small and that when the angles are near those common in practice (see Table 5), but little effect is to be noticed. In crushing granite Hersam found that greater tonnage could be handled with smooth than with medium or rough jaw faces and that the tonnage with medium faces was greater than with rough.

Table 8. Effect of speed on capacity of jaw crushers. (*After Hersam*)

Revolutions per minute	Relative tons per hour
160	100
255	144
304	171
348	174
534	179
629	246

Table 9. Effect of nip angle on capacity of jaw crushers. (*After Hersam*)

Angle of nip, degrees	Relative tons per hour
30	100
27	102
20	116
14	114

Increase in throw produces marked increase in capacity, provided the same minimum opening is maintained.

Capacity formulas. Hersam develops theoretically the formula

$$T = 54nwdsk\frac{(a^2 - b^2)10^{-6}}{(c - b)}$$

where T = tons per hr.; n = r.p.m.; a = distance between jaws at bottom, when open; b = distance between jaws at bottom, when closed; d = vertical depth of jaws; c = distance between jaws at the top when closed (width of receiving opening); w = length of discharge opening; s = sp. gr. of rock; k is a factor varying with changing operating conditions but averaging about 0.75. All dimensions are to be taken in inches. This formula does not check well with practice or with catalog figures.

An empirical formula that is relatively accurate for all except the smallest and the largest crushers is

$$T = \frac{0.6A}{R} = 0.6LS,$$

where T = tons per hr.; A = area of receiving opening in sq. in.; R = reduction ratio; L = length of receiving opening and S = width of discharge opening (set), both in inches. For small crushers the answer will be high; for large crushers, low.

Performances as reported from the mills are presented in Table 10.

At La Rose No. 2 mill (E. & M. J. 1912) one 9 × 15-in. followed by two 6 × 12-in. crushers break very hard conglomerate ore to 1-in. at the rate of 100 tons per 24 hr. Repair cost, 2 ¢ per ton. At Chuquicamata Mining Co. [illegible] a 10 × 16-in. machine breaks 135 tons per day to 2-in. at a cost of [illegible] per ton, of which [illegible] is labor; steel forms the bulk of the supply cost. At Tonopah (E. & M. J. [illegible]) a 15 × 20-in. machine crushes 15 tons per hr. to 1.5-in. [illegible] (E. & M. J. [illegible]) [illegible] 11 × 20-in. machines to break run-of-mine rock to 1.5-in. at the rate of [illegible] tons per 24 hr. At Zinc Corporation, one 12 × 30-in. crusher running at 275 r.p.m. breaks from 15-in. to 4-in. at the rate of 25 tons per hr.; one 12 × 20-in. machine set at 2 in., [illegible] the 4-in. material [illegible] a product with the following screen analysis: 31.1 per cent on 1-in., 21.7 on [illegible], 7.8 on [illegible], 5.5 on [illegible] and 10.5 per cent through [illegible] (E. & M. J. [illegible]). At Chino Copper Co. one 18 × 24-in. machine crushes 1000 tons of hard ore per 8 hr. to 2-in. (E. & M. J. [illegible]). At Mt. Morgan, one 16 × 24-in. breaks fair quartzose feed to 1.5- to 2-in. at the rate of 10 to 15 tons per hr. (E. & M. J. [illegible]). At Inspiration Copper Mining Co., an 18 × 36-in. crusher breaks 60 to 100 tons per hr. through 3-in. [illegible] with a 150-hp. motor [illegible]. At [illegible] mill, [illegible], B. C., a 24 × 36-in. machine crushes 150 tons per day to 2-in. (E. & M. J. [illegible]). At [illegible] Iron and Steel Co., Mt. Hope, N. J., a 24 × 36-in. crusher breaks 25 tons per hr. to 3-in. [illegible]. At St. Joseph L. and Z. Co., National plant, one 36 × 48-in. machine set at 4-in. breaks 4000 to 5000 tons per 24 hr. of [illegible] feed, [illegible] r.p.m., 60 to 100 hp. [illegible]. At [illegible] Corporation a 32 × 72-in. crusher breaks 160 tons per hr. to 10-in. (E. & M. J. [illegible]). At Johns-Manville a 60 × 84-in. machine handles [illegible] tons per 8 hr. to 10-in. [illegible] is held to 18° on account of the slippery character of the feed. Weight of crusher, [illegible] lb. (E. & M. J. [illegible]). At Chile Copper Co. two 60 × 84-in. crushers with rope drive are used for 10,000 tons per day; the capacity of each is 1200 tons per hr. to 10-in. [illegible]

Power consumption per ton of ore crushed is considerably greater in small than in large crushers. Up to 36-in. width of receiving opening (gape) the tons per hp.-hr. consumed ranges from 0.7 in the smaller sizes to 1.6 in the 36-in. machines. From 36-in. to 60-in. gape, the tons per hp.-hr. increases from about 1.3 to 1.8. For 60-in. gape, 2.5 tons per hp.-hr. is a fairly conservative figure. These figures are all based on a reduction ratio of 6 : 1 and on a continuously busy crusher. If a smaller reduction is practiced, tons per hp.-hr. will be increased, roughly in inverse ratio.

At Mt. Morgan a 24 × 16-in. machine set to discharge at 1.5- to 2-in. required 20 to [illegible] hp. to crush 10 to 15 tons per hr. If the crusher ran idle for any considerable portion

of the total running time, tons per hp.-hr. dropped materially. A 24 by 36-in. crusher set at 4.5-in. minimum with 1-in. throw and capable of crushing 80 to 90 tons per hr. was run at one plant 10 hr. per day and crushed 42 tons per hr. Average power consumption was 92 hp., giving but 0.45 ton per hp.-hr. Heller (*99 J 399*) states that the average jaw crusher consumes about 70 per cent. of its total power draft while idling, 50 per cent. is probably nearer the correct figure.

Fig. 24 represents the results of a test showing the fluctuation in power drawn by an 18 × 30-in. Blake jaw crusher. For the second and third minutes practically no feed was coming to the crusher and the average power drawn was about 14 hp. From the fourth minute to the end of the test the crusher was breaking from 8- to 10-in. maximum lumps to pass a 4-in. screen at the rate of 100 tons per hr. with an average power consumption of about 28 hp. Fifty per cent. of the average full-load power is, therefore, consumed in running the crusher light and must be charged against tons crushed.

Fall through the machine proper is about twice the gape. To this must be added the additional drop necessary to get feed to the machine and product away. If chutes are used, they may not safely be set at less than 45°.

Calumet and Hecla (*100 J 11*) uses a special crusher with 3-ft. 6-in. fall for 24-in. gape and 4-in. set. This has been found a great aid in freeing the crusher when mass copper clogs the jaws.

Lost time. The average percentage of lost time in the mills due to causes chargeable to the jaw crushers themselves, such as repairs and renewals, clogging and its attendant difficulties, is less than one per cent. Renewal of jaw and cheek plates and re-babbitting of bearings are the principal causes of lost time. When the crusher is planned to run one or two shifts per day only, as is done in a majority of mills, renewals and repairs are handled in the off shifts. In such cases substantially no delay is chargeable to the jaw crushers in most plants.

Attendance. The usual practice is a man to each machine. Rarely one man attends two machines. The principal duty of the attendant is to regulate the feed rate and to pick powder, steel, and waste. When the crusher is fed by dumping carloads or skip-loads of rock directly into the jaws no picking is possible, but the attendant must see that material does not bridge, or break up such jams as occur.

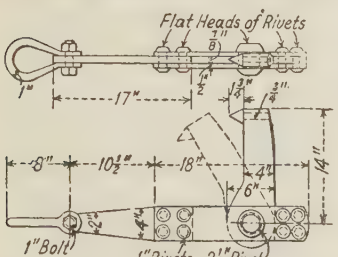

Fig. 26.—Hook for jaw-crusher feeding.

Crane service. See Sec. 23, Art. 12, for general discussion. Less than 50 per cent. of mills reporting had such service.

Feeding jaw crushers. Jaw crushers should be fed regularly and up to capacity, if possible. It is well not to bury them, since bridging at the mouth occurs easily and this necessitates digging out in order to get the flow of rock started again. Fig. 26 shows a power-actuated hook for removing lumps from the crusher jaws. Some such provision is an economy. Ample provision should be made to prevent pieces of rock from dropping into the actuating mechanism, or serious accidents may occur.

Breaking point is provided in most coarse crushers to take care of excessive loads caused by introduction of material, such as metal, that cannot be handled. In Blake breakers the usual breaking point is one of the toggles.

In crushers not specially provided, the usual effect of a stoppage under full working load with power on is either to crush the babbitt of the pitman or to throw the belt or both. If the belt does not throw off and there is not a satisfactory overload circuit breaker on the driving motor, a burned-out motor will result. Recently the provision of an overload circuit breaker on the motor, which, in case of an overdraft of power, due to clogging, cuts off the power and stops the motor, has been frequent.

Size of product. With ordinary rocks about 20 per cent. of the product will stay on a square-mesh screen whose aperture is equal to the average set of the crusher (mean between minimum and maximum throat openings); about half of the product will pass a square-mesh screen whose aperture is half the size of the crusher set. Experience at COPPER RANGE (*95 J 947*) is that primary jaw-crusher product (– 4-in.) is more even-sized if fines are not screened out ahead of the crusher, since slabs do not pass through so readily under this circumstance.

Cost of jaw crushers (1925) was 9.5 to 10 cents per pound for small machines and 8 to 9 cents for large machines. Operating cost is best estimated from the data given on power consumption, attendance and wear. These items make up about 90 per cent. of the total cost. For rough estimates, 8 to 10 cents per ton for small crushers to 2 to 3 cents for large are outside figures.

Dodge breaker (Fig. 27) differs essentially from the Blake in that the movable jaw is pivoted at the bottom. In the original Dodge type shown in the figure the movable jaw was mounted on the short arm of a lever whose fulcrum was the swing-jaw shaft (*K*) and the long arm (*B*) was actuated by an eccentric (*L*) on the drive shaft. Adjustment of the size of discharge was effected by shims (*S*). In later designs toggles and pitman have been used to actuate the swing jaw, as in the Blake type and the only difference between the two types becomes the essential and important one of the place at which the swing jaw is pivoted. Sizes and essential operating data of Dodge breakers are given in Table 11.

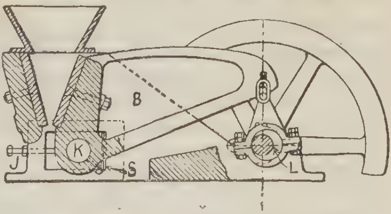

FIG. 27.—Dodge jaw crusher.

Table 11. Operating data for Dodge crushers

Size of receiving opening, in.	Weight, pounds	Capacity, tons per hour				Revolutions per minute	Horse-power
		Size, inch	Tons	Size, inches	Tons		
4×6	1,100	0.75	0.5	....	....	300	3
6×9	3,200	0.75	1.5–2.5	1.5	3–5	250–300	4–6
7×11	5,500	....	....	1.5	6–8	250–300	7
8×12	5,900	0.75	3–5	1.5	7–10	250–300	10
11×15	14,000	0.75	6–8	1.5	10–20	250–300	15

The Dodge breaker, due to the manner of pivoting the swing jaw, is forced to do its greatest work at a point on the working end of the lever farthest from the fulcrum. This makes it most uneconomical in the use of power. The capacity is low as compared to the Blake by reason of the rela-

tively small movement at the throat. It has the further disadvantage that there is difficulty in nipping the material being crushed and as a result lumps tend to fly out of the jaws.

The Dodge-type breaker is made in smaller sizes than the Blake and is, therefore, suitable for small sample plants where power consumption is so small as to be unimportant, and where uniformity in size of product, caused by the small throw at the throat, is of distinct advantage.

8. Gyratory crushers

The gyratory crusher consists essentially of a fixed crushing surface in the form of a frustum of an inverted cone around the axis of which gyrates a movable crushing surface, which has the shape of a conical frustum in erect position. The material to be broken is fed into the downwardly-converging annular space between these two crushing surfaces, it is crushed when the surfaces approach, and the crushed material falls through when they recede. The machine is built in three types, known respectively as the suspended-spindle type, the supported-spindle type and the fixed-spindle type. The first is the best known and most used; the second is fast disappearing; the third is coming into favor and in the future will dispute the field with the first type.

The sizes of suspended- and supported-spindle gyratory crushers are indicated by numbers which are usually one-half or slightly less than one-half the gape of the receiving opening, expressed in inches. Whether the spindle is suspended or supported is indicated by a letter suffix to the number, *K* usually indicating suspended spindle and *D* supported. In the fixed-spindle type the number is equal to the gape in inches. Length of receiving opening is stated as the circumferential distance, measured along the outer edge of the receiving opening, between adjacent faces of the spider arms, multiplied by the number of spider arms. This length is approximately eight times the gape in the lever-type crushers in sizes below No. 9 and seven times the gape in the larger sizes. Thus a No. 4-D crusher is of the supported-spindle type with a receiving opening roughly 8 × 64 in. and a No. 21-K is suspended-spindle type with 42 × 294-in. receiving opening.

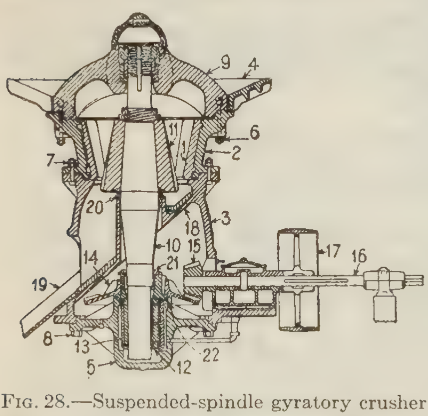

Fig. 28.—Suspended-spindle gyratory crusher.

Suspended-spindle gyratory is shown in Fig. 28. The main frame carrying the concaves (*1*) is made up of the upper shell (*2*), the lower shell (*3*), the hopper (*4*), and the bottom plate (*5*). These four parts are rigidly bolted together with heavy bolts (*6*), (*7*) and (*8*). The upper shell carries the concaves (*1*) and the two-armed spider (*9*). The spindle (*10*), carrying the breaking head (*11*), is suspended at its upper end from the spider. The lower end of the spindle passes through the eccentric sleeve (*12*), which runs in a vertical bearing (*13*) set in the bottom plate. Rotation of the eccentric sleeve is accom-

plished by means of bevel gear (*14*), bevel pinion (*15*), shaft (*16*), and pulley (*17*), driven by belt from the source of power. The axis of the spindle thus suspended and driven describes the surface of an acute cone whose apex is within the spider and the amplitude of whose base is determined by the eccentricity of the sleeve (*12*). At the same time, the spindle, being free to rotate around its own axis, rotates slowly; in the same direction as the travel of the spindle when the crusher is empty, in the reverse direction when the crusher is working. Rock to be crushed is fed into hopper (*4*), and slides down into the converging space between the concaves and the breaking head. The pieces fall as far as their size allows, then seat against the crushing surfaces, where they are broken by the movement of the mantle toward the concaves. As the mantle recedes the fragments fall to a new seat and are again crushed as the mantle approaches the concaves at the point where they are resting. When material is finally broken so that it will pass the lowest annular space between the breaking head and concaves, it falls into the annular chute (*18*), in the lower shell, and discharges through chute (*19*). Dust and grit are kept away from the gears and eccentric bearing by the dust cap (*20*), resting on the diaphragm (*18*), which is cast in the lower shell, and also by the dust collar (*21*) placed directly above the eccentric bearing. Access to the gear chamber is made possible by removable doors in the bottom shell. Access to the eccentric bearing is gained by lowering the bottom plate.

Shell is built up of heavy iron castings. The joint between the upper and lower portions is a tapered fit and is heavily flanged. The bolt holes in these flanges are drilled in such a manner that the upper shell may be turned on the lower shell, if desired. The lower shell is heavily flanged at the bottom to form a base for supporting the crusher and for bolting to foundations. All parts of the shell that are subject to wear are lined with replaceable parts. The bottom shell should be so cast that the space between the bottom of the breaking head and concaves and the highest point of the diaphragm or annular chute is as large as possible, in order to prevent clogging by slabs of rock. Discharge chute on the opposite side from the drive, as shown in Fig. 28, is known as STANDARD ARRANGEMENT. RIGHT-ANGLE DISCHARGE, with the center line of the discharge chute in a plane at right angles to the axis of the driving shaft, is furnished if desired. With such discharge, a RIGHT-HAND CRUSHER is one in which the driving pulley is on the right when the discharge chute is faced; a LEFT-HAND CRUSHER is the reverse of this.

Bottom plate is made of cast iron, heavily ribbed, in order to furnish a strong and rigid bearing for the gear-driven eccentric sleeve. It is so bolted to the flange of the lower shell as to allow it to be dropped in the foundations by means of long threaded bolts depending from the lower half of the shell. A track is provided in the foundation on which the bottom plate may be slid out to one side after dropping, to facilitate work on the gear and eccentric.

Hopper is made of cast iron heavily ribbed. In the larger crushers it is sectionalized so that only the inner ring need be removed in order to allow removal of the spider. In most crushers the hopper is so arranged that it is not necessary to remove it in order to remove the concaves; in others the inner section of the hopper projects over the concaves, the argument for such construction being that it lessens bridging of rock above the crushing zone. In large crushers the hopper is lined, usually with cast-steel sectional plates.

Spider is made of cast iron in small crushers and of cast steel in the largest crushers. Since it carries the fulcrum of the crushing lever and is two-armed only, it must be very heavy and be strongly bolted to the top shell in order to prevent overturning or breakage under lateral stresses. It should be so shaped that it forms an arch over the receiving opening of such height that the largest piece of rock that can enter the receiving opening can pass under it freely, if bridging and clogging of the crusher are to be prevented. In some crushers the base of the spider is a continuous ring forming the inner circle of the hopper, but such construction results in more breakage than when the spider is not an integral part of the hopper (*113 P 336*). Sometimes the spider arms are broadened out at the ends to give a large base for secure bolting to the upper shell. Spider arms should be protected by wearing shields unless the crusher is so fed that only occasional particles of rock come into contact with them.

Spindle or main shaft is the lever by means of which the crushing force transmitted through the eccentric bearing is applied to the rock. It must, therefore, be of great strength

and capable of withstanding a continuous succession of shock loads. It is made in most crushers of hammered, open-hearth steel, specially heat-treated, turned and polished. For extremely heavy work it may be made of special alloy steel. It is usually made to taper toward both ends, thus giving maximum cross-section and strength at the point of greatest stress. One maker hollow-bores the spindle in order to remove any defects or cracks due to the original forging, that might work outward. Threads are cut at the upper end to accommodate the adjusting nut and also at a place near the upper end to accommodate the nuts that lock the mantle. Key seats are ordinarily cut under the breaking head and adjusting nut.

Suspension bearing is of different detail in different makes of crushers, although of the same principle in all. The underlying idea is to bring the suspending surface as near to the point of no-movement as possible. In the suspension bearing shown in Fig. 29 a steel sleeve (*a*) held in place vertically by the adjusting nut (*b*) rides on the wearing ring (*c*) within a wearing sleeve or bushing (*d*), both carried by the spider. Adjusting nut (*b*) can be keyed into any desired position on the shaft.

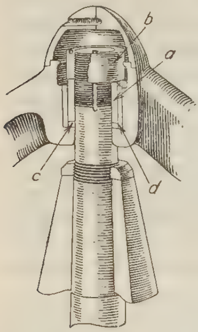

FIG. 29. — Suspension bearing for gyratory crusher.

Eccentric sleeve transmits the crushing force to the lower end of the spindle. It therefore works under high pressures and should have as large a bearing surface as possible. In all crushers the sleeve is carried in a well in the bottom plate. In most makes the eccentric is babbitted inside and out with special hard babbitt; in one make, bronze bushings are substituted for babbitt. The inner surface of the bottom plate surrounding the eccentric sleeve is bushed. The gear is keyed or riveted to the eccentric sleeve. The eccentric sleeve rides on a wearing ring of brass, bronze, or steel. In most crushers the eccentric sleeve has cylindrical faces, but in one make the inner face is spherical and engages a spherical ball on the spindle. The argument in favor of this construction is that it is self-aligning and affords a greater area of contact than the cylindrical eccentric.

Gears are made of semi-steel or high-carbon steel, cast. Provision is made, by varying the thickness of the wearing rings or by adjustment of the countershaft bearing, for taking up a small amount of wear in gear and pinion. Fitting the main gear down over the head of the eccentric sleeve and keying it thereto would seem to be better construction than that in which the gear is riveted onto the eccentric.

One manufacturer makes a gearless crusher, in which the usual gear is replaced by a horizontal pulley (*112 J 593*). This arrangement allows the spindle to be driven at a higher speed than with gears, which is an advantage in secondary-crushing service. On the other hand, the drive is bad mechanically. The crusher has not had sufficient trial to determine its utility.

A high-speed gyratory (*109 J 194*), actuated by a mechanism similar to that employed in the Mitchell screen (Sec. 5, Art. 7) has been exhibited in model size and in that size had high capacity and remarkably low power consumption. It has not, however, progressed beyond the experimental stage.

Countershaft bearing is made extra long and is cast as an integral part of the bottom shell or may be made adjustable in order to take up wear on gear and pinion. An outboard bearing of the usual ball-and-socket type is furnished.

Drive pulley in older crushers was loose on the shaft and transmitted power through pins to an auxiliary hub keyed to the shaft. The purpose of this arrangement was to furnish a breaking point. Modern crusher construction, however, eliminates this feature and the driving pulley is made extra heavy, with clamped hub keyed onto the drive shaft. In the largest crushers rope drive is sometimes used. Small crushers are belted to transmit one horsepower per inch of belt traveling at 1000 to 2000 ft. per min., reckoned on installed horsepower; the corresponding figures for large crushers are 400 to 500 ft. per min.

Data as to the different sizes of suspended-spindle gyratories available, compiled from the publications of the principal manufacturers, are given in Table 12.

Supported-spindle gyratory has the spindle supported on a wearing button (*1*) (Fig. 30) in the bottom plate, the spider serving merely to prevent horizontal movement of the upper end. The amplitude of the movement of the spindle on its support is greater in this than in the suspended-spindle type with consequent greater wear and power consumption. As a result,

this type is disappearing. Table 13 shows the sizes available. Weights and rated capacities are less than for corresponding sizes in the suspended-spindle type.

A supported-spindle machine with eccentric at the upper end of the spindle appears in patent literature, but has never advanced beyond the paper stage.

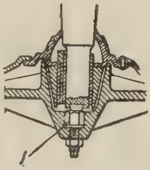

Fig. 30.—Support of spindle in supported-spindle gyratory.

Fixed-spindle gyratory (Fig. 31) is at present made by one manufacturer only (Smith Engineering Works) and goes under the name of Telsmith breaker. It differs from the types already described in that spindle (*a*) is rigidly fixed top and bottom and the movement of the crushing head (*b*) is effected by an eccentric sleeve (*c*) running between the spindle and the crushing head itself. Discharge of rock is vertical; a discharge chute is no essential part of the crusher proper. Lubrication is effected by a pump (*d*) operating in an oil well (*f*), oil being thus forced by pipes to all sliding surfaces. The frame and spider are made of cast steel and as a result of this fact and the vertical shortening made possible by applying the moving force directly under the crushing head rather than at the end of a spindle acting as a lever (as in the other types of gyratory), the weight for a given size-reduction and capacity are less than in the other types.

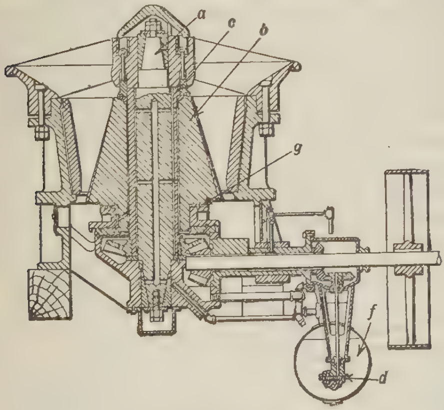

Fig. 31.—Fixed-spindle gyratory crusher.

The fixed-spindle gyratory is becoming a recognized competitor of the suspended-spindle machine. It has been installed as a primary or secondary coarse crusher in many recent plants and has given satisfaction. Its relatively small height lends itself to rugged construction and the short spindle cuts down the clear height that must be left above the machine for convenience in repair work. The fact that the length of stroke is the same on both large and small pieces is an advantage when soft, tough material is being crushed but is unnecessary and may be disadvantageous with hard and brittle materials.

The sizes available and performances to be expected are given in Table 14, compiled from manufacturer's data.

Concaves for gyratory crushers are made almost without exception of manganese steel, very occasionally of chilled iron for light service. In larger crushers each stave of the concaves is sectionalized, allowing discard of one part while retaining the rest. At some plants the staves are sectionalized in two parts, making the upper two-thirds of chilled iron and the lower third of manganese steel. Concaves are supported either at the bottom by a sectional removable iron rim resting on a shelf on the lower shell or by means of lugs or ribs that are cast on the back near the top and fit into a groove in the top shell. After being set in place the concaves are backed by hard zinc or hard babbitt poured in between them and the shell. Frequently the lower edge of the concaves is beveled in order to increase the amount of metal behind the point at which maximum crushing is done. Life

Breaking head is, like the concaves, made either of chilled iron or manganese steel. Chilled-iron breaking heads are solid and keyed directly to the spindle. When manganese steel is used, a soft iron or semi-steel core is keyed to the spindle and a mantle of manganese steel is slipped on over this. The mantle is held down on the core by means of some self-tightening arrangement. Two devices are commonly used for this purpose. GUN-LOCK MANTLE is illustrated in Fig. 32. The core itself is keyed to the spindle by means of feathers in keyways (*a*). On the outside of the core two grooves (*b*) are cut at 180°, and the bottom of the core is finished to a curve whose highest point is at the bottom of grooves (*b*). The mantle is ground to fit closely on the head and is cast with lugs (*c*) that slip down the grooves (*b*) and pull the mantle tightly onto the core as the mantle turns with respect to the spindle. Another SELF-TIGHTENING MANTLE is shown in Fig. 33. In one form the nut is made of three pieces: piece (*1*), pinned to the top of the mantle and carrying on its inner surface a left-hand thread; piece (*2*) having a corresponding left-hand thread on the outside to engage piece (*1*) and a right-hand thread on the inside to engage the thread on the spindle; and piece (*3*) with a right-hand thread inside. When the mantle loosens it works round on the core and imparts its motion to nut (*1*). If the direction of motion is such as to cause the left-hand thread to unscrew, the mantle is thereby pressed down onto the core. If, on the other hand, the motion is such as to cause the left-hand thread to tighten, then nut (*2*) is caused to move down on the spindle, again pressing the mantle down on the core. With this type of mantle zinc is used to make a tight joint between the mantle and the core. Some manufacturers recommend the use of zinc or babbitt keys to prevent the solid heads or cores from turning on the spindle; others use an ordinary steel feather key. One maker uses self-tightening nuts to force the core down on a tapered spindle and eliminates keys. The use of keys would, however, seem to be the better practice, notwithstanding the difficulty in drawing keys when a head is to be changed. A DISADVANTAGE of the use of self-tightening lock-nuts is that large pieces of ore jammed in the mouth of the breaker may loosen the control nut. This happened frequently on a primary gyratory at MOOSE MOUNTAIN (*99 J 973*).

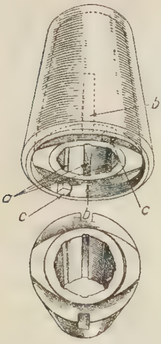

FIG. 32.—Gun-lock mantle for gyratory crusher.

In large crushers the mantles are frequently made in two parts. The greatest wear comes at the bottom and the amount of metal that must be wasted can be decreased by making the bottom part replaceable while retaining the old upper part. Mantles are made corrugated or smooth. The corrugated head is best for coarse breaking; a smooth head is best if a large proportion of fines is desired or if the feed to the crusher is already relatively fine. Life of mantles is given in Table 15.

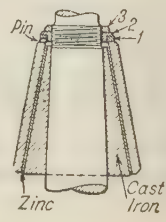

FIG. 33. — Self-tightening lock-nut for gyratory mantle

Lubrication. In all crushers the eccentric bearing runs submerged in oil. Capillarity is depended upon in some crushers to draw oil from the bath

into the bearing surfaces while in others a forced feed is used. The main countershaft bearing is generally ring- or chain-oiled with overflow from the reservoir into an oil sump in the bottom plate. It is probable that the best lubricating system is one in which an efficient forced feed of heavy oil is employed. Extrusion of this oil around the bearings aids to keep grit and dust out.

Adjustments of gyratory crushers are (1) width of discharge opening, (2) throw, and (3) speed. Width of discharge opening is changed in the suspended-spindle crusher by raising or lowering the spindle by means of the adjusting nut (*b*), Fig. 29. A ring bolt

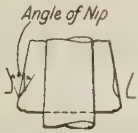

Fig. 34.—Change in nip angle with wear of breaking head and concaves.

is furnished to engage the top of the spindle, which is then hoisted by appropriate means, allowing the adjusting nut to be readily moved as desired. The change is made in the supported-spindle type by raising the supporting nut (*1*) (Fig. 30). In the fixed-spindle type the adjustment is made by changing the thickness of shims (*g*), Fig. 31.

Range of adjustment in width of opening is limited because of the fact that the nip angle is markedly increased as a result of wear of the breaking head. This is shown in Fig. 34. This increase in nip angle causes a great decrease in ability of the crusher to discharge, with corresponding decrease in capacity. If more than a small adjustment in width of discharge is required, it must be obtained by using thicker and shorter concaves and breaking head.

Throw is less than in jaw crushers. It is adjustable only by changing the eccentric sleeves. It should be greater in large crushers than in small and should be greater for relatively soft and tough rocks than for hard and brittle rocks.

Mn Manganese steel. *a* Increased at least 50 days by use of oversize heads.

Speed may be varied throughout wide limits. Increased speed is not accompanied by the marked increase in vibration and shock that occurs with jaw crushers. The lowest speed compatible with the capacity required is most economical within certain operating limits. A tendency to clog by reason of the sticky character of ores may often be overcome by increase in speed, thus increasing the sharpness with which the head recedes from the concaves.

Speed, throw, capacity, reduction ratio and power consumption are closely related. If the reduction ratio is increased when the crusher is working near maximum capacity, the speed of the crusher must be increased to keep up the capacity. This will be accompanied by a considerable increase in power consumption. If the machine is sufficiently over-motored so that the change brings no perceptible strain on the driving equipment, it is well to watch for heating of the eccentric, as any marked increase in the direction above noted over the figures recommended by the manufacturers is likely to result in burned-out bearings. If increase in reduction ratio is to be effected without mechanical troubles, it should be accompanied normally by decrease in speed and a decrease in the amount of material in the crushing zone. This latter decrease is accomplished by shortening the head and concaves and by decreasing capacity.

a When new. Wears to 2 or 2½ in. *b* Very hard rock. *c* Still in good condition. *d* With one set of concaves; used another 90 days with a second set of concaves. *e* Set up or renewed, according to wear. *f* Old ball-mill liners. *g* Superintendent reports that the machine requires almost no attendance. It has stalled on steel several times without breakage. *h* ¼-in. sheet iron. *i* Babbitting eccentric and changing mantles and concaves. *j* Have given complete satisfaction. *k* Upper ring chilled cast iron, lower manganese steel. *MS* Manganese steel. *CCI* Chilled cast iron.

Data on mill performances are given in Tables 15 and 16 and in the following notes.

At Roseberry mill, Slocan, B. C., a No. 2-D Gates (6 × 50-in.) crushes 150 tons per 24 hr. from 2-in. to 1-in. (*114 J 677*). At the Tonopah Belmont mill a No. 4-B short-head machine (5 × 77-in.) is used to break from 2-in. to 1-in. at the rate of 500 tons per 24 hr. The concaves for this machine weigh 666 lb., cost $88 (1915), and wear for two years, crushing 75,000 tons. They are set out at the end of 6 months and turned end-for-end at 12 months. The mantle weighs 536 lb. and has the same life (*52 A 96*). A No. 5 crusher (10 × 80-in.) at the Trojan mill, So. Dak. (*114 J 763*), set to 1.75-in., crushes 400 tons per 24 hr. of the oversize on a 1.5-in. grizzly. At the Santa Barbara (Mex.) mill of the American Smelters Securities Co. a No. 5 McCully crusher (suspended-spindle) set at 1.5-in. breaks the run-of-mine oversize on a 1-in. grizzly at the rate of 500 tons per 24 hr. (*112 J 1050*). At St. Joseph Lead Co. mill, Bonne Terre, Mo., three No. 5 gyratories are used to crush 2100 tons run-of-mine ore per 24 hr. The ore, principally dolomite, sizes to 11.1 per cent. on a 10-in. screen, 12.6 per cent. on 8-in., 7.6 per cent. on 6-in., 32.5 per cent. on 4-in. and 36.2 per cent. through 4-in. It is split on a 7.5-in. grizzly and the oversize is sent to one No. 5-K (suspended-spindle type) gyratory while the undersize is split between two No. 5-D (supported-spindle type) machines. A sizing test of the combined discharge is 12.9 per cent. on 3-in. screen, 11.4 per cent. on 2.5-in., 17.6 per cent. on 2-in., 15.7 per cent. on 1.5-in., 14.9 per cent. on 0.35-in., 9.9 per cent. on 0.079-in., 3.5 per cent. on 0.0041-in. and 1.6 per cent. through 0.0041-in. (*57 A 423*). (See also Table 12.) At the Shattuck-Arizona mill a No. 5 Telsmith (fixed-spindle) crusher set at 1 5-in. breaks 400 tons per 24 hr. of +1.5-in. run-of-mine ore. This crusher has handled 500 tons per day (*110 J 759*). At Barnes-King Development Co. mill (*60 A 98*) a No. 5 Telsmith breaks 15.3 tons per hr. to 0.4 per cent. on 3-in. screen with a power consumption of 1.1 kw.-hr. per ton and at a cost (1917) of $0.046 per ton. At the head house of the Ellison shaft of the Homestake mines four No. 6 gyratories set at 3-in. are used to crush about 25 tons per hr. each of rock passing a jaw crusher set at 4.5-in. and remaining on a 3-in. grizzly (*114 J 760*). At New Modderfontein (So. Africa) four No. 6 gyratories set to 2-in. take 1200 tons per 24 hr. run-of-mine ore. Each crusher has a 60-hp. motor (*120 P 789*). At the Silver King Coalition mill (Utah) the primary crusher is a No. 6 gyratory set to 1.5-in. and handles 300 tons per day of +1.5-in. run-of-mine ore, 8-in. maximum size (*116 J 370*). At United Eastern a No. 6 Telsmith set to 2-in. takes 35 tons per hr. run-of-mine ore, 10-in. maximum size, and draws 10 kw. average load. By placing a 1.75-in. grizzly ahead of the crusher, repairs were materially decreased (*63 A 551*). United Comstock uses one No. 7½ gyratory set at 3-in. for the oversize, on a 3-in. grizzly, from 2000 tons per 24 hr. run-of-mine ore (*114 J 846*). At Hollinger three No. 7½ gyratories set at 3.5-in. handle an average of 70 tons per hr. each (90 tons per hr. maximum), when running at 144 r.p.m. of spindle and drawing 50 hp. Two work on the oversize of a 7.5-in. grizzly screening run-of-mine ore through a 14-in. grizzly, the other crushes the undersize of the 7.5-in. grizzly. This routing of ore is said to increase the gross capacity of the three crushers, especially when the ore is wet. Concaves are sectionalized transversely: the upper, of white iron, last 12 months; the lower, of manganese steel, 8 months. They are re-set every 4 months and require 1700 lb. of zinc per setting. Head centers are of cast steel, mantles of manganese steel. The latter are drawn on the shaft at 125 tons pressure after warming to 120° F. Life is 7 mo. Poured-zinc keys are used to keep the mantle and head center (core) from turning on the spindle. The product of the primary crushers is sent over a 2-in. grizzly and the oversize sent to three No. 5 crushers, two set at 2.5-in. and one at 1.5-in. The total feed to the three machines is about 35 tons per hr. Speed of spindle, 157 r.p.m. Each crusher consumes about 25 hp. The upper ring of concaves is white iron and the lower manganese steel. Life of the upper ring is 12 months and of the lower, 3 months. The concaves are re-set every four or five weeks; 900 lb. of zinc is required for a setting. (*1922 Bul. CMI 340.*) At Tonopah Belmont manganese-steel concaves for a No. 7½ crusher weigh 1120 lb. and crush 150,000 tons; a mantle weighs 1994 lb. and will crush 225,000 tons (*52 A 110*). At Alaska Gastineau four No. 8-K machines set at 2.5-in. are used to crush −5-in. jaw-crusher product at the rate of 110 tons per hr. each. Mantles are of gun-lock type and both mantles and concaves are manganese steel. Lower concaves last 8 months, crushing 16 hr. per day. Changing concaves and re-zincing requires 8 hr. The crushers are driven by clutch pulley from a line shaft (*63 A 493*) (see also Table 12). Chile Copper Co., Chuquicamata, Chile, originally put in two No. 10 crushers for primary service to handle 275 tons per hr. each from 16-in. maximum to 3-in. discharge size. They proved too small and are now preceded by two 84 × 60-in. jaw crushers (*101 J 23*). Alaska Treadwell used two No. 12-K Gates crushers followed by four No. 6-K set at 2-in. to crush about 4500 tons per day of run-of-mine ore. Sizing analysis of the product follows: 6 per cent. on 3-in. screen; 28.2 per cent. on 2-in ; 29.25 per cent. on 1-in.; 10.11 on 0.5-in.; 11.65 per cent. on 0.185-in.; 7.80 per cent. on 0.0328-in.; 2.23 per cent. of 0.0164-in.; 0.80 per cent. on 0.0116 in.; 0.65 per cent.

on 0.0082 in.; 0.65 per cent. on 0.0058 in.; 0.80 per cent. on 0.0041-in.; 0.53 per cent. on 0.0029-in. and 1.33 per cent. through 0.0029-in. (*114 P 410*). The primary crusher at New Cornelia is a No. 24-K Gates gyratory. It will take boulders 3.5 × 4.5 × 10-ft. and reduce them 9-in. at the rate of 500 tons per hr. and the discharge rate at this setting has run as high as 800 tons per hr. when the feed was free of boulders that caused clogging in the bowl. Capacity was reduced to 400 to 450 tons per hr. to 6-in. size by setting out the concaves and using a thicker mantle. Average manganese-steel consumption in this and four No. 8's following is 0.0032 lb. per ton in mantles and 0.081 lb. per ton in concaves. Average power consumption for the five machines is 0.21 kw.-hr. per ton. Four No. 8-K crushers set at slightly less than 3-in. take the oversize of a 3-in. grizzly screening the product of the primary crusher set at 6-in. The feed to each machine is between 100 and 125 tons per hr. and this is a little less than full load. These same crushers set at 4-in. and taking 9-in. feed were unable to handle the feed at the rate of 200 tons per hr. each (*63 A 509*). At Utah Copper Co. a No. 27 double-discharge machine is used to break from 54-in. maximum size to 4.5 in. (*118 P 469*).

Reduction ratio, according to manufacturers' ratings, ranges from a minimum of 5, excluding fine-crushing gyratories, to a maximum of about 9 with a general average of about 6. A greater ratio is recommended for large crushers than for small. See Table 12. In practice the apparent ratio, reckoned as the ratio of the gape to the minimum opening at the throat averages 5.78 for twenty-five crushers (see Table 15). The actual ratio, reckoned as the ratio of maximum size of feed to set of crusher averages 3.04 for nineteen suspended-spindle crushers and 4.6 for four fixed-spindle machines. The maximum apparent reduction ratio recorded from the mills is 10.6; the maximum actual ratio is 8. The minimum apparent ratio is 2.6; the minimum actual ratio 2.

Angle of nip in gyratory crushers ranges from 21° to 23° with an average very near 22°.

Capacity depends primarily upon character of ore, size of feed and discharge setting. Throw, speed, angularity of jaws, and character of crushing surfaces have a material effect. Capacities for different sized crushers according to makers' catalogs, are given in Tables 12, 13 and 14. (See Art. 7 for a discussion of the applicability of these figures to various ores.) The discussion of the effect of various factors upon the capacity of jaw crushers, as given in Art. 7, holds for gyratory crushers. The Hersam formula is supposed to be applicable to gyratory crushers as well as jaw crushers. There is no simple empirical formula that answers to results in gyratory crushing as does that given for jaw crushing. Capacities given in makers' tables are frequently far exceeded in mills although usually the excess capacity results from the feed of material much smaller than the maximum that the crusher will take, with consequent freedom from bridging and clogging. The lower figures in the lines bracketed with the parenthesis in Table 12 refer to this character of feed and are conservative for any rock other than the most tough. In such service the actual reduction ratio will rarely exceed 3.

Power consumption. Tons crushed per horsepower-hour consumed in the mills ranges from 0.31 to 11.6 in suspended-spindle machines (Table 15) and as high as 14.9 on a soft ore in a fixed-spindle crusher (Table 13). The average for 20 lever-type machines is 3.56. The high figures represent machines in secondary service when worked well up to the limit of capacity. According to field practice no greater number of tons per consumed horsepower is to be expected from large crushers than from small ones.

Figs. 35 to 36 represent the results of a power test on a gyratory crusher in actual operation. The data reported on Fig. 35 appear in columns 4 and 5 of Table 15. These figures show that the power installations called for by the manufacturers, in Table 12, are higher than need be counted on for running; they are needed, however, for starting.

Fall through machine proper is about ten times the gape for machines up to 12-in. gape. For larger machines the figure decreases with increase in

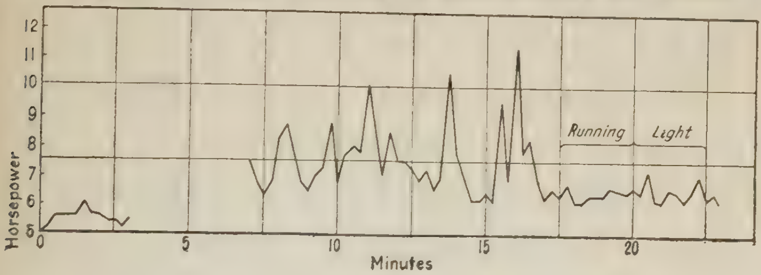

FIG. 35.—Load curve of No. 6-K Gates gyratory crusher.

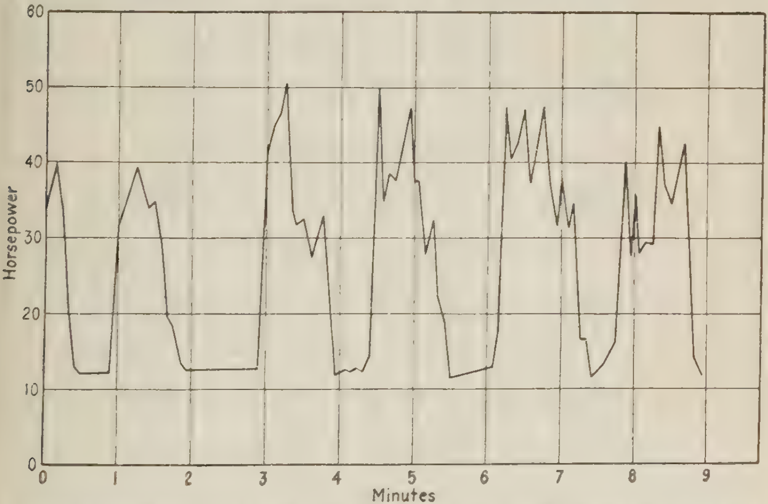
gape from 8 to 6. Closer figures for fall are given in Tables 12, 13, and 14. These figures will come within a few inches of the exact ones for crushers made by any of the leading manufacturers.



Speed of pinion shaft, 207 r.p.m.; maximum size of feed, 24-in.; largest particle in product, 4-in.; rate of feed during test, 99.6 tons per hr.; average hp., 26.2 (decrease chart readings by 2.7 hp. for power draft of a conveyor driven by the same motor).

FIG. 36.—Load curve of No. 8 Gates gyratory crusher.

Lost time. Average percentage of lost time in the mills due to causes chargeable to the crushers themselves, such as repairs and renewals, clogging and its attendant difficulties, is less than 1 per cent. Renewal of mantles, concaves and chute liners and re-babbitting of the eccentric bearing are the principal causes stated. One plant reports 8 per cent. lost time due to clogged chutes. In this plant a 12-in. crusher was discharging a product, a considerable proportion of which was more than 4 in. in size; an extremely large tonnage was being put through and clogging was to be expected unless a large drop was allowed from the concaves to the highest point of the diaphragm. The majority of the crushers reported are planned to work but one or two shifts per 24 hr., thus leaving at least one shift free for all minor repairs. With good planning and with a sufficient supply of repair parts on hand, such operation will practically eliminate lost time.

J = Flake-type jaw crusher. G = suspended-spindle gyratory.

Attendance. Usual practice is one man per machine to two or three machines per man. Where the gyratory crusher is the primary crusher there should be an attendant for each machine to remove waste. Where the gyratory is a secondary crusher little or no actual attendance, apart from oiling and watching for trouble, is necessary.

Crane service. See Sec. 23, Art. 12, for general discussion. Substantially 50 per cent. of the mills reporting had crane service to the gyratory crushers and 30 per cent. more were served with a crawl and chain block. There can be no doubt that some such service should be provided.

Feeding. The crusher should be fed regularly and as nearly as possible up to capacity. If the feed contains particles near the largest that the crusher will receive, it is wise not to bury the crusher, as bridging may easily occur and necessitate digging aside a lot of heavy material. However, bridging is much less likely to occur in gyratory crushers than in jaw crushers and many more of the former are fed so as to be buried. The majority of plants report the crushers fed by chutes or over stationary grizzlies. Other methods reported are by belt or pan conveyors, drum feeders and shaking grizzlies. Pan conveyors are probbly the most satisfactory method for feeding initial crushers. The chute-fed crushers mostly occupy a secondary position in the mills, taking feed from a primary crusher.

Breaking point is not generally provided in modern gyratory breakers. The big breakers will pass almost any piece of steel that gets to them without stalling or breakage. Small crushers will generally slip a belt before breaking and if the motor is properly safe-guarded against overload, this is a fairly satisfactory method of procedure. In older crushers a breaking pin was provided in the driving pulley. Overload circuit breakers are probably the best method of providing against damage with machines directly connected to a motor.

Size of product. Between 10 and 20 per cent. of the product of a gyratory will remain on a square-mesh screen of the same aperture as the set, the higher percentage with slabby material; between 50 and 55 per cent. of the product will remain on a square-mesh screen whose aperture is half the set.

Cost. Price of gyratory crushers in 1925 ranged from 7.5¢ per lb. for No. 21 size, and 8¢ for No. 7½ to 18¢ for No. 2. Upwards of 90 per cent. of the cost of crushing is made up of power, labor and wearing parts. If crushers are run to capacity the crushing cost should range below 6¢ to 8¢ per ton for the small crushers and 1.5¢ to 2.5¢ for large.

9. Comparison of jaw and gyratory crushers

Table 17 compares the crushers of the two types built by one manufacturer. It shows that, when worked to capacity, the price of a gyratory varies from 27 to 77 per cent. of that of a jaw crusher capable of the same reduction in particle size; also, that under the same circumstances, the gyratory will crush from 1.7 to 4.3 times as much rock as the jaw crusher per installed horsepower. But, when the quantity of rock to be crushed per hour is within the capacity of one jaw crusher of the proper gape, then the price of a gyratory for the same work ranges from 1.3 to 2.5 times that of a jaw crusher. The work at WITHERBEE-SHERMAN presented in Figs. 24, 35 and 36 indicates that the power consumption of a jaw crusher idling is roughly 50 per cent. of that at full load and the full-load consumption about 50 per cent. of the installed horsepower; corresponding percentages for the gyratory are 30 and 60 per cent. Applying these figures to Table 17 it appears that for machines reducing to 4-in. or less, power consumption per ton crushed is less in the jaw crusher. In coarser crushing, products from 5- to 12-in. sizes, power consumption per ton crushed is less for gyratory than for jaw crushing. Repairs, cost of installation, and loss of head are all greater for the gyratory than for the jaw crusher at all sizes. It may, therefore, be concluded that for crushing quantities that can be handled by one jaw crusher the jaw crusher is the more economical installation on all counts; that for coarser crushing the gyratory will consume less power per ton crushed, but will cost more to install, to keep repaired, and will require greater expenditure for elevation of material. It has the advantage of allowing expansion in capacity, it can be set higher than a jaw crusher on account of absence of vibration, and it can be fed from all sides. On the other hand, if the rock is clayey or fibrous or does not break freely, it is more likely to clog. The shape of the crushing zone of the gyratory prevents the discharge of large slabs unbroken, such as can pass through a jaw crusher, and hence the gyratory product will be more uniform than that of a jaw crusher.

Analysis of good practice shows that the following empirical relation will give a rough indication of of the proper crusher to use, based on tonnage and size considerations only, *viz.:* If the hourly tonnage to be crushed divided by the square of the gape expressed in inches yields a quotient less than 0.115, use a jaw crusher; otherwise a gyratory.

INTERMEDIATE CRUSHING

Intermediate crushers are those used to take the product of the breakers and reduce it to sizes best suited for feeding to fine crushers and grinding

machines. The group includes stamps, rolls, disk crushers and reduction gyratories. Under certain rather unusual circumstances any of these may be used as a final crusher, *e.g.*, steam stamps in Lake Superior copper mills, gravity stamps in amalgamation plants, rolls in dry magnetic plants, disk crushers preparing oxidized copper ore for leaching, etc. Rolls are most widely used. Disk crushers are direct competitors of rolls; they are relatively recent members of the group and for certain types of work are superior to the older form (see p. 312). Gravity stamps are the oldest type and were for many years pre-eminent as a combined intermediate and final crusher in gold mills. They still hold an important position because of the large number yet operating in mills built ten to thirty years ago, but with the exception above noted they have now been relegated entirely to the field of intermediate crushers where they come into direct and generally unsuccessful competition with rolls, and disk crushers. The reduction gyratory is the latest addition to the group and is so new that its importance cannot yet be accurately adjudged.

10. Reduction gyratory. Cone crusher

Reduction gyratory is made both in the suspended-spindle and the pillar-shaft (fixed-spindle) types. The latter type is similar to the pillar-shaft breaker except that the flare of the breaking head is greater in the reduction gyratory and the concaves flare downward instead of converging, as in the cone crusher (Fig. 37), in order to maintain the required nip angle. This construction has the advantage of giving a large area of discharge opening for a given set of the crusher and consequently a larger capacity than otherwise. The usual sizes are 4-, 6- and 10-in. gape. This is a new machine and its capacity is not established. Capacities given by one manufacturer range from 24 tons per hr. to ¾-in. to 48 tons to 1½-in. for a 6-in. machine and from 80 tons per hr. to 1½-in. to 135 tons per hr. to 2½-in. for a 10-in. machine.

Symons cone crusher (Fig. 37) is of the flaring-bowl gyratory type of intermediate crusher. The crushing head (*a*) is supported on a large hemispherical bearing (*b*) and is gyrated by a long, ball-supported eccentric (*c*), driven by the usual bevel gearing. The stationary crushing surface (*g*) is attached to the main frame (*h*) by means of bolts (*j*) that act against a nest of springs (*i*) which compress and allow the head to lift when an uncrushable body enters. A distributing plate (*d*) is mounted on the upper end of the spindle under the feed opening (*e*). Set may be adjusted while running by loosening lock nuts and revolving the head (*f*) by means of nuts (*k*). Sizes, capacities and power consumption, as stated by the manufacturer, are shown in Table 17*a*.

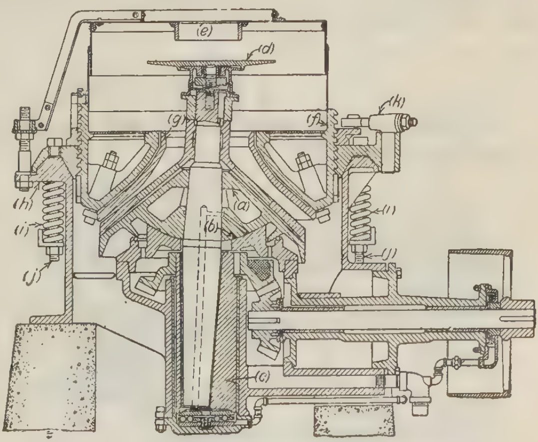

Fig. 37.—Cone crusher.

Performance. This crusher has not yet (Jan., 1927) been in the field long enough to supply many data on performance, but those given below show it a likely competitor of fine-crushing gyratories, disk crushers and rolls. At Utah Apex a No. 4 machine crushes −4+1-in. feed to −1-in. at the rate of 60 tons per hr. It is driven at 525 r.p.m. (driving pulley) by a 75-hp. motor and is estimated to draw 50 hp. No weaknesses have developed in 3 months' running. At St. Louis Smelting and Refining Co. a 7-ft. machine set ¼ to

5/16 in. takes the product from a jaw crusher set 4 to 5 in., containing slabs up to 14 in. square, at the rate of 150 tons per hr. with a consumption of 130 hp. Capacity falls to 140 tons per hr. with damp ore. Screen test of product is: On 0.742-in., 3.5 per cent.; 0.525, 14.7; 0.371, 21.8; 0.263, 13.2; 0.185, 10.7; 0.131, 8.0; 0.0082, 24.8; −0.0082-in., 3.3 per cent. The +⅜-in. material is all flaky with the minimum dimension less than the crusher set. With a feed passing 3-in. ring capacity reaches 180 tons per hr., the +⅜-in. material in the product decreases and the power draft is 100 hp. The machine has passed large pieces of steel without choking or breakage. A 4-ft. machine at the same plant set ¼ to 5/16 in. crushes −3-in. gyratory product containing 28% − ⅜-in. material at the rate of 100 tons per hr. and draws 65 hp. The product sizes: +0.742-in., 2.2 per cent.; 0.525, 9.4; 0.371, 19.6; 0.263, 16.4; 0.185, 12.5; 0.131, 7.8; 0.0082, 27.1; −0.0082, 5.0 per cent. C. G. Dresser (*PC*) states that it is contemplated at this plant to replace four No. 6 gyratories and two 54 × 24-in. rolls by two 7-ft. cones.

11. Disk crushers

The disk crusher is made in two forms, known respectively as the horizontal and vertical types.

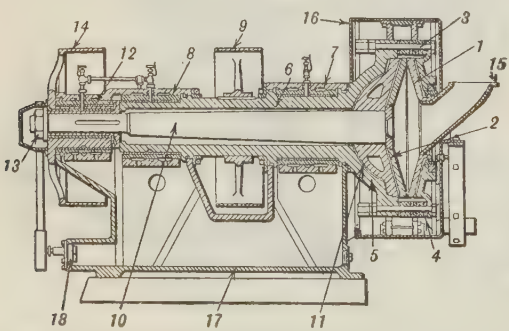

Fig. 38.—Disk crusher, horizontal-spindle type.

Horizontal disk crusher (Fig. 38) consists essentially of two opposed concave conical crushing surfaces (*1*) and (*2*), of large apex angle, rotating in the same direction at substantially the same speed around horizontal axes. The mechanism is so arranged that any two given points at corresponding positions on the surfaces of the opposing cones alternately approach and recede from each other. This action is accomplished as follows: Disk (*1*) is attached by means of bolts (*3*)

and spacers (*4*) to the bell-shaped end (*5*) of the hollow horizontal shaft (*6*). This shaft is carried in bearings (*7, 8*) in the main frame of the machine and is positively driven by means of pulley (*9*). Disk (*2*) is carried on the end of the solid shaft (*10*). This shaft and the disk are supported by the hemispherical bearing (*11*), eccentric (*12*) and thrust nut (*13*). The solid shaft is not positively rotated. The center of eccentric sleeve (*12*) is not coincident with the center of revolution of shaft (*10*). Pulley (*14*) rotates in a direction opposite to that of pulley (*9*) and at a speed somewhat more than twice greater. With no rock in the machine the inner disk rotates only to the extent that motion is induced by bearing friction, but as soon as rock is introduced the movement of the outer disk is transmitted through the rock to the inner disk and the speed of rotation of the inner disk comes up substantially to that of the outer.

With the end of shaft (*10*) furthest from the disk set eccentrically to the center of shaft (*4*), each point on the surface of disk (*2*) would approach and recede from the corresponding point on the surface of disk (*1*) once in each revolution of the disks, if there were no independent motion of the eccentric. By driving the eccentric in the opposite direction to that of the outer disk and at the same rate of speed, each point on the surface of either disk would approach and recede from corresponding points on the other disk twice per revolution. Further increase in relative motion between the two pulleys causes further increase in the number of approaches and recessions of corresponding points on the disks per unit of time or per revolution of the main shaft. Since the eccentric pulley is normally driven at something over twice the rate of the main pulley, there are normally something over three crushing actions at each point on the surface of the disk for each revolution of the main pulley. Feed is introduced by pipe (*15*) through the center of the outer disk and drops to a bearing between the disks. Centrifugal force, friction, and the pinch of the disks then act on the particles with the result that some material at least, is carried up and, after crushing, thrown out at the periphery well above the lower segment. This increases the area of discharge from the crushing zone and therefore increases capacity. It is to be noted also that the cross-sectional area of the crushing zone increases toward the region of finer crushing, so that crowding is lessened and production of fines minimized. Discharged material is caught by the housing (*16*) and discharged through a chute at the bottom. The lower part of main frame (*17*) is made oil- and dust-tight and acts as a reservoir in which oil, circulated by means of pump (*18*) is collected after seeping through the various bearing passages. The crusher is made in four sizes, named by the diameter of the disks as 18-, 24-, 36- and 48-in.

In the earlier disk machines much trouble was experienced by breakage of disks by steel and other unbreakable material in the feed. All disk machines in practice should be guarded against tramp iron by magnets. The use of manganese and chrome steel for disks has done away with much of the breakage trouble and any iron that gets past powerful guard magnets is readily taken care of. Non-magnetic manganese steel from steam-shovel dipper teeth cannot, of course, be caught by magnets.

At New Cornelia this is guarded against by checking up on dipper teeth as each train load of ore leaves the shovel and redoubling the watch at the crushing house when a tooth is missing. Guard magnets cannot be used with magnetite ores, which is a serious impediment to the use of disk crushers on such material. At Replogle Steel Co. fine-grinding disks are guarded by a screen in closed circuit with rolls. Steel large enough to hurt the disks is diverted to the rolls and kept in the roll circuit until broken down to a size that the disks can handle. At Moose Mountain (*99 J 975*) a man watches the feed. Steel that gets past him has never broken an important part, but stalls the machine and blows the motor fuses.

Size of product. From 10 to 30 per cent. of the product of the horizontal-spindle machine remains on a square-mesh aperture equal to the disk setting, and from 55 to 65 per cent. is coarser than half the disk setting.

Vertical disk machine is shown in Fig. 39. The upper disk (*1*) is carried by means of bolts (*2*) and spacers (*3*) on the table (*4*), which is carried on rollers and driven by gear (*5*) and pinion (*6*) from the main shaft (*7*). The lower disk (*8*) is carried on plate (*9*), the lower surface of which is a spherical segment and rests on the spherical wedge (*10*). Both (*9*) and (*10*) are carried along by rotation of table (*4*). The stem (*11*) of wedge (*10*) is moved in a small horizontal circle by eccentric (*12*) through the gears (*13*) and (*14*) from shaft (*7*). The direction of rotation of the eccentric is opposite that of the upper disk, hence the relative motion of the disks is the same in this machine as in the horizontal-spindle type. The upper disk is held to its work by springs (*15*), designed to compress when an unbreakable substance enters the machine and thus guard against disk breakage. This provision, together with a magnet ahead of the machine, prevents most of the troubles chargeable against the early disk machines. Feed is introduced through spout (*16*) onto the lower disk and thrown out by centrifugal force until it wedges between the disks. After breaking, it again travels outward and is subjected to further crushing operations until it finally can escape into the outer chamber and discharge through spouts. The eccentric speed is so high (350 r.p.m.) and the resulting number of crushing movements so great that but few particles escape being subjected to a crushing pinch near the periphery of the disks and hence the discharge size is substantially that of the minimum setting of the disks. Gears and bearings are enclosed in dust-proof housings as in the case of the horizontal machine and are lubricated by a forced feed from pump (*17*). The vertical-spindle machine is made with 36-in. and

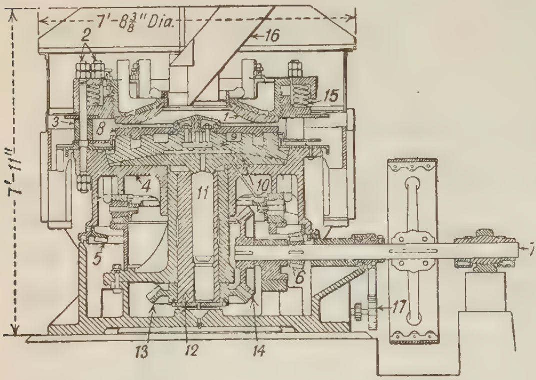

Fig. 39.—Disk crusher, vertical-spindle type.

48-in. disks. By use of different disks it may be fitted for either coarse or fine crushing.

Performance. CHILE COPPER Co uses twenty-four 48-in. vertical-spindle disks to crush 13,000 tons per 24 hr. from 1.5-in. to 12 per cent. on ⅜-in. (*123 P 849*). NEW CORNELIA uses one 48-in. vertical-spindle machine set at ¾-in. and two 48-in. machines set at ¼-in., taking the oversize on a ⅜-in. screen from the product of the first, to crush 90 to 100 tons per hr. from 3.5-in. to 3-mesh. A sizing test of the product is given in Table 20. Repairs are light on the coarse-crushing disk but heavy on the fine-crushing machines. Average power consumption for five such 3-machine sets is 0.7 kw.-hr. per ton; average steel consumption, 0.059 lb. per ton crushed; babbitt, 0.0097 lb. per ton. Cost in May, 1920, including power, repairs, and labor and including also screening and conveying was $0.09 per ton (*63 A 507*; *123 P 849*). At REPLOGLE STEEL Co. 48-in. disk crushers average 25.2 tons per hr. (maximum, 36 tons per hr.). Screen tests of feed and product are given in Table 20. Average power draft, 15 kw.; minimum, 7.5 kw.; maximum, 25 kw. At Santa Barbara mill of AMERICAN SMELTERS SECURITIES Co. a 48-in. machine set at 0.5-in. crushes the oversize on a 0.75-in. screen from 500 tons per day of −1.5-in. material.

12. Rolls

Rolls are of two general types, known as rigid rolls and spring rolls. RIGID ROLLS are the older type but are rarely used at the present time. They differ from the type to be described in that the bearings for both rolls are rigidly fixed on the frame and the rolls must stall, or something bend or break when an uncrushable particle enters.

Spring rolls are illustrated in Fig. 40. They consist essentially of two cylinders (*1*) mounted on horizontal shafts which are driven in opposite directions so that corresponding points on the cylinder faces above the horizontal plane through the shaft centers are moving toward each other. The main frame (*3*) carries the fixed bearings (*4*) and movable bearings (*5*). These bearings carry shafts (*2*) and (*6*). Near the centers of the shafts are the cores or hearts (*7*), fixed, and (*8*), removable, for holding the shells (*9*). The fixed roll is driven by pulley (*10*) and the movable roll by a smaller pulley (*11*). The movable roll is held up to the fixed roll by means of two heavy tension rods (*12*), carrying nuts that bear at one end against the movable-roll bearings, and at the other end against a nest of springs (*13*), which are seated against the main frame. The minimum distance between roll faces is fixed by the shims (*14*). The rolls are encased in a housing consisting of fixed sides (*15*), and covers (*16*), which are easily removed to permit inspection of the roll faces. Beneath the rolls a hopper (*17*) is provided to guide the discharge to a chute. A feed hopper (*18*) is bolted to the top of the housing. This hopper is fitted with replaceable distributing plates that spread the stream of feed

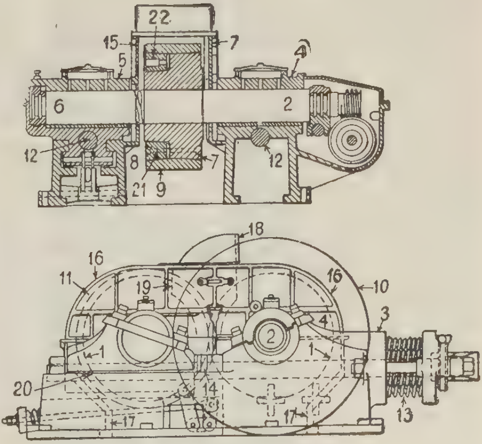

FIG. 40.—Spring rolls.

out over the full width of the roll faces. Cheek plates (*19*) are provided to protect the housing from wear of the feed stream and to prevent material from passing between the sides of the rolls and the housing without crushing. Cheek plates, roll shells, and hopper liners are made replaceable. Replaceable steel strips (*20*) are provided to protect the frame from wear due to movement of the movable-roll bearing. Table 21 is generalized from catalogs of the

a The catalogs of five principal makers are summarized. This column gives the number of makers who manufacture a given size. *b* The lightest and heaviest of the size listed. *c* Not usually by the same maker. Low speeds ordinarily correspond to the light-weight rolls. *d* The lower figure corresponds to light rolls at low speed and *vice versa*.

principal makers and gives data as to sizes, weights, speed and power consumption of rolls available without special design. Note that there is a wide diversity in weight of a given size of roll as offered by different manufacturers. The lighter rolls should be chosen only for small capacities or very easy crushing or where the first cost is of paramount importance. Heavy rolls for heavy service will repay the additional first cost in a short time in lower repair costs and continuity of operation.

Frame is cast by all makers in a single piece, usually with the lower half of the fixed bearing, the spring seat and the discharge hopper cast integral therewith. The sides of all but the smallest rolls are of box section, thus forming heavy box girders along both sides of the rolls under the bearings. The tops of the sides are machined at one end to form slides for the movable bearings and are fitted with removable steel wearing plates that protect them from the wear of the movable bearing. Cast-iron and semi-steel are the materials used for frames. The bottoms of the frames of the better rolls are planed in order to give a proper bearing on the foundation.

Bearings are made extra long and heavy in order to distribute properly the heavy forces brought upon them. Normally they are split along planes at an angle of 20° to 30° to the horizontal as shown in Fig. 40. This is done in order to prevent shearing stresses on the bearing-cap bolts by bringing these bolts into lines substantially parallel to the direction of the resultant of the forces exerted in the bearings by the roll shafts. Movable bearings are made with a long base in order to aid in keeping the movable roll in close alignment with the fixed roll. Bearings are self-aligning, allowing the rolls to swivel in order to permit a hard object to go through on one side without bending the roll shafts. Babbitt or phosphor bronze is used for lining bearings, some users preferring one and some the other. In the smaller rolls babbitted bearings are plain babbitted, in large rolls babbitted bushings are used in the lower half. With this provision the bearings can be rebabbitted by lifting the shafts but a small distance and slipping the bushings in under them. Some manufacturers provide a holding-down device for the movable bearing that prevents chattering and lessens wear on slides and bearings. Bearing caps are fitted with large reservoirs for grease or oiled waste and generous oil passages should be cut in the babbitt to allow ready circulation to all parts of the bearing.

Tension rods are made of best forged steel of ample cross-section. One end is fitted with a heavy hexagonal nut with provision for pinning in position. The other end is threaded with special thread for transmitting power and fitted with a special nut or a gear wheel that works against the spring cage. Tension rods are placed as near the shafts as possible in order to bring them as near as possible in the line of the forces resisting crushing.

Springs are of the helical type carried in cages and set to the proper tension at the factory. The tension varies from 4000 to 30,000 lb. per lineal inch of roll face. With these high pressures the rolls are practically rigid and while there is enough give when an unbreakable article passes through to save bent shafts and broken frames in most cases, there is no doubt that there are more cracked frames with high spring pressures than with low. The springs do not give until a pressure well in excess of ordinary resistance to crushing is exceeded. They take no part, therefore, in ordinary crushing. Springs are held in the cages by two or four heavy bolts to each cage. These bolts need not be disturbed when spacing the shells nor at any other time except in the event of replacing a broken cage or spring or when it is desired to change the spring pressure. Increase in spring pressure should be made with caution, as it is usually set by the maker as high as is safe.

Shafts are made of forged steel turned and polished and keyed for pulleys. In some makes of rolls shafts are interchangeable and reversible. In other makes the ends are grooved for thrust collars and fitted for lateral adjusting devices in such a way as to prohibit the interchangeable feature. Normally, the diameter of the shaft is greater in the core than elsewhere, in order to put the most metal at the place of greatest strain.

Pulleys are made of wood, cast iron, cast semi-steel, and with steel disk and cast-iron or cast-steel rim. The cast pulleys are made with split hub key-seated and with solid rim. In all cases the pulleys are balanced as perfectly as is possible. Wood pulleys or steel-disk pulleys are recommended for heavy vibrating duty such as is encountered in coarse crushing. Most makers furnish a large pulley on the fixed-roll shaft of sufficient size to transmit all of the power necessary for crushing and place on the movable roll a smaller pulley whose principal function is to keep this roll moving when there is no material passing through. If the rolls are not of the reversible type, with equal pulleys on both shafts, they must be ordered right-hand or left-hand, according to the way in which it is desired to drive them. In general, the designation right- or left-hand is made on the basis of the position of the large pulley when standing at the end of the rolls carrying the spring cages. Standing thus and facing the rolls, if the large pulley is on the left the rolls are left-hand, and *vice*

a Overloaded. *b* Choking and changing shells. *c* Midvale steel. *d* Wooden wedges. *e* Ratio of average size of feed to average size of product. *f* To pass ⅝-in. ring. *g* Grease. *h* Changing shells, babbitting bearings, alignment, choking. *i* Average. Maximum = 22; minimum = 11.8. *j* To pass 7-mm. round hole. *k* Regular shifting of feed. *l* Shaking launder. *m* Changing shells; broken gears; tramp iron. *n* One shell cast iron, life 400 days; other steel, life 300 days. Steel shell has one transverse groove, 1.5 × 0.75 in. to aid nipping. *o* Horizontal slot with fingers. *p* Tapered cores. *q* Wood and steel wedges. *r* Mild steel. *s* Changing shells. *t* To pass 0.053-in. round hole. *u* Shovel wheel. *v* Rigid. *w* Wet; per cent. water unknown. *x* Average. 18.3 maximum; 7.0 minimum. *y* Bronze. *z* No corrugations. Center grooving eliminated by turning in lathe. *A* After seven years' service ends turned down and fitted with steel bushings. *AF* Automatic fleet. *B* Fixed, 70; movable, 84. *C* Hot bearings, breaking of foundation bolts, choking. *CI* Cast iron. *CCI* Chilled cast iron. *Cl* Close, faces in contact. *Cr* Chrome steel. *D* Rolls flange and corrugate. Flanges burned off with acetylene torch. *E* Emery bricks kept on all rolls. *F* Shells slipping when thin; clutch shoes wearing.

versa. Occasionally both pulleys are placed on the same side, the stationary shaft furnished with an outboard bearing. This arrangement is much superior from the standpoint of safety and convenience.

Roll centers, cores or hearts are made of cast iron. A typical form for large rolls is shown in Fig. 40. The fixed heart (*7*) has a long tapered hub. It is pressed onto the shaft under hydraulic pressure running up to 300 tons per square inch. The movable heart (*8*) is split and drawn onto the hub of the fixed heart by bolts (*21*). The outer surface of the hearts is tapered toward a least diameter along a circumference at the central transverse plane of the roll shell when in place. The roll shell is correspondingly tapered inside. Shells are put on by first removing the movable heart and slipping the shell over the fixed heart, then drawing the movable heart tightly in place by means of bolts (*21*). Frequently the shell is expanded by heating at the time the cores are drawn together so that when cool it shrinks down on the cores. A special bolt (*22*) is provided for backing away the movable heart when necessary. One maker puts the taper on the shaft and makes the outer surface of the hearts and the inner surface of the roll shells cylindrical. The advantages claimed

of rolls—*Continued*

G Estimated. *H* Based on original tonnage where available, otherwise on total. *HCS* High-carbon steel. *J* Crucible steel. *L* Broken shells; jammed threads on tension-rod bolts; loose pulleys. *M* 0.1252 lb. per ton. *MLS* Manual lateral shifting. *Mn* Manganese steel. *N* 0.0543 lb. per ton. *P* Numbers in italics refer to columns in Table 21*a*. *R* See sizing test, conical ball-mill feed, Table 55*a*, No. 16. *S* Edison type, rigid, corrugated shells. *T* High spots burned off at intervals. *U* Edison type, spring, corrugated shells. *V* Minimum dimension of largest particles of feed taken as 0.6 times aperture of screen that passes feed. Where set of rolls is not given it is taken as 0.6 times aperture of screen that passes all of product. *W* These settings do not accord with size of product. *X* Feed size reckoned at 0.9 times short dimension of slot. *Y* Based on total tons passing. Where set of rolls is not given it is taken as 0.6 times aperture of screen passing all product. When set close the mean opening is taken as one-half of 0.6 times (= 0.3 times) the aperture of the screen passing all product. *Z 29 IMM 238*. + Indicates that attendant has other duties.

for this method of construction are strengthening of the shaft at the point of maximum strain and greater ease in rolling the shells. A serious disadvantage lies in the fact that the expensive shaft is subjected to a possibility of considerable wear with resulting necessity for replacement. In smaller rolls wood or wood and steel wedges are used between the shell and a solid cylindrical core.

Shells are made of high-carbon steel rolled similarly to locomotive tires, or of forged chrome steel rolled or bored to size and taper, or, less frequently, of manganese steel ground to proper shape. In old practice the shells were made of chilled iron, but on account of the impossibility of making a uniformly hard shell, this material pits rapidly and badly with resultant loss in crushing efficiency (see Sec. 4, Art. 27). For light service, rolled high-carbon steel shells are entirely satisfactory. An advantage claimed for them is that, due to the fact that the surfaces are not extremely hard, there is less failure to nip than is encountered with harder shells. Likewise they do not crack readily and therefore can be worn down very thin before replacing.

There is great difference in steels from various sources. The products of local or little known shops are particularly to be regarded with skepticism. Ferguson (*50 A 290*) gives

the following chemical analysis and physical properties of a good rolled-steel tire: C, 0.65 to 0.80 per cent.; Si, 0.15 to 0.30 per cent.; S, 0.04 per cent.; P, 0.05 per cent.; Mn, 0.6 to 0.85 per cent.; ultimate stress, 125,000 lb. per sq. in.; yield point, 72,000 lb. per sq. in.; elongation, 10 per cent.; reduction in area, 15 per cent. On three tests with these tires the wear was 1.06, 3.8 and 4.25 lb. per ton crushed. These figures are all much above normal. (See Table 22.) The six new tires weighed 4494 lb. total and 1640 lb. total when discarded. Manganese-steel shells have longer life on coarse feed than chrome-steel, but on fine feed there is much less difference and the advantage is with the cheaper chrome steel. Life of shells under varying conditions of service is given in Table 22.

In a mill where rolls are used for crushing different sizes of material, partly worn shells from fine rolls may be transferred to the coarse rolls, provided these are of the same size, since the loss of efficiency in coarse rolls, due to slight pitting, is much less than in fine rolls. Flanging and pitting of roll shells are prevented or materially slowed down by proper attention to lateral adjustment. Emery bricks held constantly against the face of the rolls diminish corrugation. At Van Roi mill (*101 J 465*) the use of such bricks tripled the life of fine-roll shells. In South-eastern Missouri flanged shells are taken off and ground or turned down in a lathe, according to whether they are manganese or rolled steel. A 54 × 20-in. shell can be turned down in 20 to 30 hr. dependent upon the extent of corrugation (*57 A 346*). For rolls with wide faces the shells are sometimes made in two rings. At Ohio Copper Co. (*99 J 748*) shells for 60 × 24-in. rolls are in two sections, one 10-in. width and the other 14-in. This construction induces grooving at the joint.

Housing is made of cast iron or sheet steel. In most cases the lower part is cast integral with the frame and provided with a flange for bolting on the upper part. Most makers provide the upper part with cast-iron ribbed sides and sheet-steel cover. Hinged inspection doors of sheet steel or of canvas ribbed with steel straps are provided over both rolls. The housing is made as nearly dust-proof as is practicable. The shaft openings are covered with special devices to prevent emission of dust and grit. The sides of the housing are made sufficiently strong and stiff to carry the weight of the feed hopper and in some cases also to carry a feeder.

Cheek plates are made of hard iron or, rarely, of special steel. They are bolted to the inside of the housing in the hopper-shaped opening formed by the sides of the housing and the upper surfaces of the rolls. They should be made capable of lateral adjustment by means of bolts projecting through the housing so that they can be properly crowded up against the edges of the rolls to prevent the passage of uncrushed material between the sides of the rolls and the housing. Life of cheek plates is given in Table 22.

Feed hopper is placed to one side of the opening between the rolls in order to deliver the stream as nearly as possible to the center of the opening. It should be furnished with distributing plates for spreading the stream of feed across the full width of the roll faces. Adjustable side plates are also a convenience. Liner plates for the hopper are made of hard iron or manganese steel. The life of liner plates is from 30 days to several years. Commonly they are changed with the cheek plates.

Adjustments possible in well-designed rolls are (*a*) the distance between roll faces, and (*b*) lateral adjustment of one or both roll shafts. Adjustment of the distance between faces, or roll setting, is accomplished by changing the distance between the faces of the nuts at the two ends of the tension rods and by change of the total thickness of the shims placed between the forward end of the movable bearing and the frame. In making this adjustment it is important that the shafts be kept parallel. In most rolls this is accomplished by pinning the nuts at one end of the tension rods and so arranging the nuts at the other end that they are both moved equally and dependently by the adjusting mechanism. Fig. 41 illustrates the adjusting mechanism on one make of rolls in which the adjusting nuts are turned by spur gears operated by intermediate gears from a common pinion. This mechanism draws

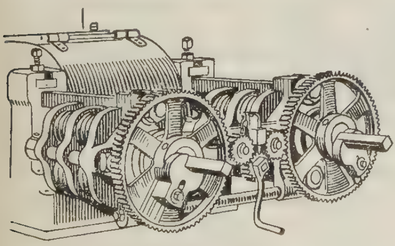

Fig. 41.—End adjustment for setting rolls.

the movable-roll bearing up against a block of shims whose total thickness is that necessary to keep the roll faces a predetermined distance apart. As roll shells wear down the shims are changed to allow the roll shafts to be drawn closer together and thus compensate for wear. This end-adjustment mechanism provides for backing the movable roll away from the fixed roll in order to free the rolls in case of clogging. It also allows the rolls to be backed away from or drawn up to the shims while running.

Side adjustment is necessary to prevent flanging and circumferential corrugation. In order to prevent flanging the range of side adjustment must be such that either edge of both rolls can be made to run for a part of the time, at least, on the face of the other roll. To prevent corrugation rolls should be shifted through a distance of about 0.6 times the diameter of the largest particles in the feed. Lateral adjustment is accomplished manually or automatically. At SILVER KING COALITION (*99 J 615*) the life of shells on fine-crushing rolls was increased from 90 days to 2 years by installing rolls with manual fleet and adjusting every 16 hr. The objection to manual adjustment is that it is likely to be forgotten or purposely neglected by the roll operator and that a short period of neglect may result in ruining the surface of a pair of shells. The only objection to automatic lateral shifting lies in the difficulty of making a simple, durable and certain shifting mechanism. This objection bids fair to be overcome.

Several operators report satisfactory performance of the Traylor mechanism shown in Fig. 42. In this device the worm (*C*) cut on one end of the fixed-roll shaft (*B*) operates the worm wheel (*D*) on the transverse shaft (*E*), set below the main shaft. The worm (*T*) on shaft (*E*) in turn drives the worm wheel (*G*) on shaft (*H*). A worm on the other end of shaft (*H*) drives the worm wheel (*K*) on shaft (*L*). Shaft (*L*) carries an eccentric sleeve (*N*), fitted to a slide in a machined recess in the thrust collar (*O*). This collar carries grooves into which fit corresponding collars cut on the end of shaft (*B*). Lateral motion of the eccentric sleeve (*N*) is thereby transmitted to the shaft (*B*) which is caused to move backward and forward along the line of its axis through a distance determined by the throw of the eccentric (*N*). This mechanism is enclosed in a dust-proof case cast integral with one side of the roll frame. The case carries bearings for the various shafts. Variation in amount of lateral movement, or FLEET, is accomplished by changing the eccentric shaft (*L*). The chain of gears is such that one complete cycle of roll-shaft movement is completed in about 30 min.

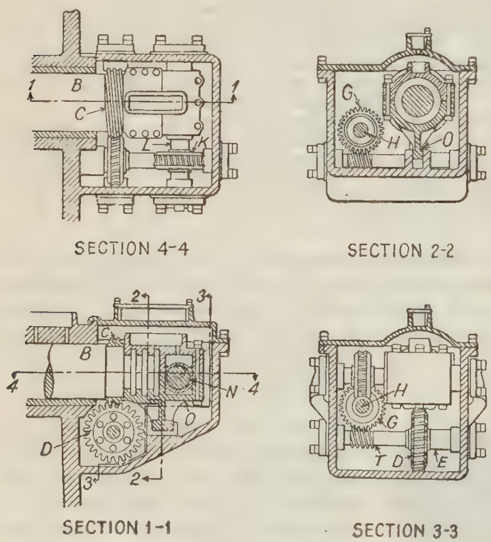

FIG. 42.—Traylor automatic lateral adjustment for rolls.

Sectionalizing. Most makers will furnish rolls up to 30-in. diameter sectionalized so that the heaviest piece does not exceed 300 or 350 lb.

Requirements for ideal rolls are that they should be rugged, simple in construction, compact and the working parts should be readily accessible; worn parts should be capable of easy change with as little dismantling of the apparatus as possible. Springs should exert a pressure sufficient to crush the hardest rock and yet should be sufficiently flexible to pass unbreakable substances without bending the shafts or breaking the castings. A substantially dust-proof housing and large dust- and grit-proof, well lubricated bearings should be provided. The mechanism for adjustment for distance between roll faces should be capable of rapid and easy operation, in order to facilitate clearing the rolls in case of clogging, it should not necessitate a change in spring pressure, and it should advance both sides simultaneously in order to maintain proper alignment of shafts. If possible there should be automatic lateral adjustment of one of the roll shafts. Fleeting devices, however, add considerably to the first cost and thorough investigation of their trustworthiness should be made before purchase.

Performances at a number of mills are shown in Table 22.

Angle of nip (n) is the angle formed by the tangents to the roll faces at the points of contact therewith of particles to be crushed. This angle is shown as angle ACB, Fig. 43, a. Particle P, which is to be crushed, is assumed to be spherical. If r is the radius and D the diameter of the rolls, d the diameter of particle and s the distance apart of roll faces along the line joining the centers of the rolls, the following relation holds:

$$\cos\frac{n}{2} = \frac{r + s/2}{r + d/2} = \frac{D + s}{D + d}.$$

Neglecting gravity, the particle is acted upon by forces applied at the points of contact in directions indicated by the lines F (Fig. 43, b). These forces can be resolved (considering one side only) into a normal force N and tangential force T. If the normal and tangential forces are resolved into their horizontal and vertical components respectively, it will be seen that the particle will be drawn down when the vertical component of T, acting downward, exceeds the vertical component of N, acting upward. The limiting condition is reached when the vertical components of T and N are equal but opposite in direction. Under this condition the particle will neither be nipped nor thrown out of the rolls but will ride in the hopper formed by the converging faces. With this condition the following equations may be written:—$N_v/N = \sin n/2$; $T_v/T = \cos n/2$. Dividing the first equation by the second, $\tan n/2 = TN_v/NT_v$. But under the assumption $T_v = N_v$. Therefore $\tan n/2 = T/N$. From the ordinary relations of mechanics T/N = tangent of the angle of friction. For stone on iron the coefficient of friction (= tangent of the angle of friction) is about 0.3. Substituting this value in the above equation, $\tan n/2 = 0.3$; $n/2 = 16° 42'$ and $n = 33° 24'$.

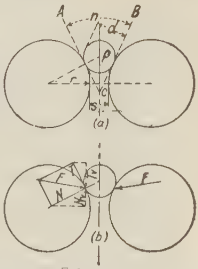

Fig. 43.—Nip angle of rolls.

In practice the nip angle rarely exceeds 25°. The average nip angle in 45 sets of rolls reported from the mills was 17° 26′. The range in angle was from 5° 36′ to 35° 30′. The angle averaged 23° 21′ for feeds coarser than 2 in. 19° 26′ for feeds between 1 and 2 in., 14° 38′ for feeds between 0.5 and 1 in., and 11° 25′ for feeds smaller than 0.5 in. The variation is due, how-

ever, to the use of large rolls with small feeds in order to get capacity and the angles used with coarse feeds may be taken as the safe average figure.

The angle of nip varies with the diameter of the rolls, the diameter of the particle and the set of the rolls. In order to nip large particles, rolls of large diameter must be used, or the reduction ratio must be small. When feed of a given size is not being nipped, the usual alternatives are to install larger rolls or to increase the distance between the roll faces and consequently increase the size of product. A third expedient reported by one plant was to cut a transverse groove in one of the roll shells. The effect was, of course, to increase the nip angle at this particular point.

At American Graphite Co. smooth shells would not nip. The difficulty was eliminated by drilling eight sets of four 1.5-in. holes at equal angular distances around the roll faces (*120 P 569*).

Diameter of rolls required for various sizes of feed is given in Table 23. The largest commercial roll is 78-in. diameter and rolls smaller than 24-in. are rarely used outside of the laboratory.

a Allowing 25° nip angle.

Reduction ratio is a phrase commonly used in discussing crushing performances. It has no exact quantitative significance, but may convey useful qualitative information. As defined by *Truscott* in connection with rolls, it is the ratio of the size of the largest feed particle to the smallest distance between the roll faces, *i.e.*, the set. As used frequently in the field, it is the ratio of the smallest aperture passing all of the feed to that passing all of the product. Another basis of expression is the ratio of the average size of feed to the average size of product. (See Sec. 22, Art. 5.) In the relation of size reduction to angle of nip and strain on crushing machinery, the first expression is the most significant; in stating the duty of rolls and their performance in a flow-sheet, the second; in judging the relation between duty and power consumed, the third. When rolls are set close, the first method is, of course, inapplicable, without knowledge of the mean roll spacing while crushing, and

this is not, normally, available. The mean ratio of reduction in average size from Table 22 is 3.4; individual figures range from 1.2 to 16.8.

Speed of rolls is limited by the ability to nip and by the weight and ruggedness of the rolls. Hence the allowable speed is affected by the diameter of rolls, the kind of ore, method of feed, reduction ratio, and size of feed. Speed should be lower for hard, tough rock than for soft and brittle rock, less for dry feed than for wet feed, less for coarse feed than for fine, and less for a large reduction ratio than for a small, nip being the controlling factor in each case. The speeds reported range from 382 ft. per min. for rolls 24-in. diameter, to 2060 ft. per min. for rolls 72-in. diameter. Practice tends to keep below 900 ft. per min. with rolls up to 36-in. diameter, below 1000 ft. per min. for 42-in. rolls, and not to exceed 1500 ft. per min. with 56- and 72-in. machines, more or less independently of the other factors; higher speeds are dangerous to springs, shafts, frames and foundations.

At Miami Copper Co. 55-in. rolls taking −3.5-in. feed are run at 100 r.p.m. and the same size roll taking −2-in. feed is run at 115 r.p.m. At Engels (*123 P 183*), crushing to 1 in. in 54 × 24-in. rolls, capacity was increased and power decreased 40 per cent. by a decrease in speed from 110 to 54 r.p.m.

Cornish rolls, gear-driven at 50 to 100 ft. per min. peripheral speeds, are occasionally met. The allowable nip angle is much greater at these slow speeds and the product is likely to contain more fines than the product of high-speed rolls because of the tendency toward choke feeding and restriction of discharge.

Capacity of rolls. The theoretical capacity in tons per hr. is given by the equation

$$C = \frac{NDWSG}{18{,}300},$$

where N = the number of revolutions per minute; D = the diameter of the rolls, W = the width of face and S = the set, all in inches; and G = the specific gravity of the rock being crushed. The development of this equation is based on the assumption of a solid ribbon of crushed material whose length is 60 times the distance traveled by a point on the roll face in one minute, whose width is the width of the roll faces and whose thickness is equal to the set of the rolls. With open setting the actual capacity never reaches the weight of the "theoretical ribbon." The theoretical ribbon is more nearly approached the smaller the set. Table 22 indicates that for rolls set coarser than 1-in., a capacity of about 5 per cent. of the theoretical ribbon is to be expected. For sets between 0.25 in. and 1 in. the average performance is 15 to 20 per cent. of theoretical, while for sets less than 0.25-in. the average is 20 to 30 per cent. of theoretical with free feeding. With choke feeding in closed circuit with a screen, from 100 to 250 per cent. of theoretical ribbon is to be expected, the set of the rolls being assumed as 0.3 times the screen aperture. The rolls may be set in actual contact or with some small space between faces, but the mean cross-section of the ribbon is, of course, greater than the setting, since the rolls recede against the spring pressure at short, irregular intervals. The percentage of theoretical ribbon that can be crushed is about 50 per cent. greater in the case of soft, easily crushed rocks than with hard, tough rocks.

Power consumption, in terms of tons of new feed per horsepower-hour, depends upon the kind of rock being crushed, the size reduction, the size of

product and the amount of circulating load, if any. Average figures from Table 22 are 0.4 ton per hp.-hr. to less than 0.25-in. size; 0.6 ton per hp.-hr. to a size between 0.25- and 0.75-in.; 0.75 ton per hp.-hr. to a size between 0.75-in. and 1-in.; 1.6 tons per hp.-hr. for a product between 1- and 1.5-in. and 2.8 tons of a product between 1.5- and 2-in. These figures disregard the size reduction and the character of the rock, on the basis that in the number of examples given these average. Reference should be made directly to the table when the character of the rock to be crushed is known to be similar to that at one of the mills reporting, since variations from the average are large.

Feeding. Rolls must be fed at a constant rate and with the stream distributed over the full width of face in order to get maximum capacity and efficiency. If the feed stream is not distributed over the full face, circumferential grooving occurs under the feed point and the amount of crushing done at one pass rapidly decreases. If the feed is not constant in quantity but comes in surges or rushes, the rolls are liable to choke and stall or, if the driving equipment is sufficiently heavy to prevent this, they spring apart and pass a mass of material only partially crushed. This causes chattering and excessive wear on slides and babbitt; it produces a greater tonnage of circulating feed, if the rolls are run in closed circuit with a screen; and makes it impossible to reach maximum capacity. Types of feeders designed to insure constant feed rate are described in Sec. 20. It is good practice to drive the feeder from the roll shaft so that when the roll stops the feed will stop, but in such a case the residue in the feeder must be removed before the roll starts again. If the feed contains a large percentage of clayey material, rolls are liable to choke.

It is best to balance the speed of the rolls and height of drop of the feed in such a way as to bring the feed particles to the roll faces at a speed as near that of the roll faces as possible. In this way there is no differential movement of particles and roll faces with resulting polishing and difficulty in nipping.

Rolls may be FREE-FED or CHOKE-FED, the former phrase indicating freedom of movement between particles resting in the V of the rolls prior to nipping, the latter that the particles at this point are piled up to such a depth that no free movement exists. In free feeding each particle is broken substantially individually and crushing is practically uniform and continuous; in choke feeding masses of material are rolled through intermittently, the roll faces springing apart to permit their passage. In this compression of the mass of rock there is much abrasion between particles which results in a less granular product than that from free crushing. Except in the case of the largest rolls, choke feeding can be practiced only with material already crushed to ¼-in. or less.

Rolls are ordinarily run dry, especially at the present time when they have been displaced by ball and rod mills for re-grinding middling.

The fine rolls at MIAMI were originally designed for wet crushing, but in operation they worked better with dry feed, so the water was cut off the feed and added to the discharge (*115 P 565*). These rolls have now been removed.

Dust production with dry feeding is a distinct disadvantage; the dust is difficult to control and causes trouble with belts and bearings.

Size of product. The lower limit of size for efficient roll crushing is not clearly established. Where a product passing a 10-mesh screen is all that is desired, it is probably more economical to complete the crushing in rolls than

to install rod or ball mills. If a product finer than this is desired, ball or rod mills will crush more economically than rolls and the weight of practice is to carry roll crushing not finer than 0.75-in. In many cases ball mills are taking feed much coarser than this. Rolls can be made to crush to 20-mesh or finer, but to do so, must be set close and run "choked." Such practice is highly uneconomical, on account of wear and tear and power consumption.

Graded crushing is an operation of gradual reduction in size by means of a series of crushers, each set with a smaller discharge aperture than the preceding, with material fine enough to pass the following crusher removed between the crushing steps. The purpose is to minimize production of slimes. The size reduction in successive steps in graded crushing is usually small, i.e., of the order of 2 or 3. The alternative extreme is to break down with as big steps in reduction ratio as the size and strength of the crushing machines will permit, with no removal of fines ahead of successive crushers, except that the last crusher in series is in closed circuit with a limiting screen.

During the years before the introduction of flotation processes in base-metal milling, when minimum sliming was essential to maximum recovery, the tradition that graded crushing was necessary was established, apparently with very little experimental evidence. Recently an exhaustive investigation by the New Jersey Zinc Co., crushing a sphalerite ore with granitic gangue from 1-in. to 0.1-in. maximum size in rolls, showed that the amount of −0.025-in. material produced was the same, within a range of about 2 per cent. of the weight crushed, irrespective of the number of steps or the presence or absence of intermediate screening. Tests in the laboratory at Columbia University have shown that the sizing test of the product of a pair of rolls with a given set is substantially the same with a given rock, irrespective of the size of feed, provided only that the rolls are free crushing, that they will nip the particles, and that there is no undersize present in the feed. The significance of the last restriction lies in the fact that if the various feeds contain different amounts of undersize these will have different effects on the screen tests of the products, even though they pass through without any breaking. These facts would seem to establish definitely that there is no advantage from graded crushing and intermediate screening in free crushing in rolls.

Corrugated rolls differ from the plane rolls already described in that the shells are corrugated transversely. Corrugated shells are used in a few metal mills, usually where the feed is too large to be nipped by rolls with plane shells.

At Hollinger (*1922 Bul. CMI 343*) a set of 40 × 20-in. transversely-corrugated rolls set at 0.75-in., running at 110 r.p.m. and drawing 45 hp. takes the product from three gyratories, one set at 1.5-in. and the others at 2.5-in., at the rate of 125 tons per hr. Finger gears are used on these rolls to keep the corrugations in mesh. The driving motor has a double-throw switch to allow reversal in case of clogging. The shells are manganese steel, 4 in. thick. One set weighs 4730 lb. and crushes 200,000 tons, so that steel consumption is 0.024 lb. per ton crushed.

Character of roll product. Two cases arise, *viz.*: (*a*) The rolls are set spaced a definite distance between faces. (*b*) The faces are set close.

In the first case the feed ranges, in general, upwards of 75 per cent. coarser than the set of the rolls (average of nineteen cases at random was 83 per cent.); the product ranged in the cases investigated from 4 per cent. coarser than the set to 78 per cent. coarser, average 45 per cent., which gives an average reduction in the percentage of material coarser than the set of 45 per cent. In the same operations the percentage of material finer than half of the roll setting

averaged 30 and ranged from 2 to 66 when there was an average of less than 5 per cent of such material in the roll feed.

With close setting the average reduction in maximum particle size is close to one-half, this average applying as well where the maximum size in the feed is 20-mm. as when 1.5-mm. The average percentage of material in the product that is less than half of the maximum particle in size is about 60; the range is between 30 and 80. In the cases investigated this average represented an increase in such material over that present in the feed of about 2½ times.

Applying these generalizations to specific problems: (*a*) Given a feed containing 75 per cent. +1-in. material to be crushed in rolls set 1-in.; the average product would contain 45 per cent. +1-in. material and 30 per cent. −½-in. material. (*b*) Given a feed containing 5 per cent. of +20-mm. material to be crushed in rolls set close; the average product would contain about 5 per cent. +10-mm. size and about 60 per cent. −5-mm. material.

Cost of roll crushing. The elements of cost are power, labor, repairs and lubrication. See p. 309 for data on power consumption. One man can attend to from 3 to 12 sets of rolls; the average in 20 plants investigated, where the roll tender had no other duties, was 6. Repairs may be estimated at about twice the cost of roll shells. Consumption of lubricant ranges from about 2 to 30 lb. per 24 hr. On the basis of these quantities the cost of crushing to −¼-in. should not exceed $0.07 per ton in small rolls (36-in. or less diameter) nor $0.045 in large. Coarse crushing will cost considerably less on account of smaller power consumption and labor cost.

Applicability. Rolls are the most widely used intermediate crushers for handling feeds smaller than 1.5-in. and delivering products down to 0.1-in. In such service they have large capacity, low power consumption and relatively low repair costs. They are rugged, reliable, simple in construction and easy to repair.

Selection of rolls. 1. *Open-circuit crushing.* Determine the set necessary (p. 311). From this and the small dimension of the largest feed particles (This averages 0.6 × aperture of the hand screen that passes the particle, if of granular shape; 0.4 to 0.5 times, if slabby.), calculate the diameter required for an allowable nip angle (p. 307). Determine from Table 21 (p. 288) the widths of face available; choose a suitable speed (p. 309; Tables 21, 22); then substitute in the equation for theoretical capacity (p. 309) Allow for the difference between actual and theoretical capacity (p. 309; Table 22), and determine the number of machines needed. If one or less, the size chosen is indicated, but with a large reduction ratio and small tonnage, two smaller rolls in series may cost less both for maintenance and operation. If more than one machine is indicated the alternatives are: two or more smaller machines, in series (which will change diameter requirements) or in parallel, or fewer and larger machines, with more favorable nip angle.

2. *Closed-circuit crushing.* The set must be less than 0.7 times the aperture of the screen closing the circuit (pp. 311, 516). The percentage of oversize in the original feed to the circuit that will return after one pass through rolls and screen will vary, depending on the ore, roll setting, ratio of roll setting to screen aperture, and screen efficiency; it is rarely less than 40 per cent. and sometimes above 80 per cent. The circulating load may be estimated (based on a percentage return experimentally determined, or estimated) from $S = a/(1 - r)$, (a = tonnage of oversize in original feed, per unit of time, r = percentage return expressed as a decimal, and S = tonnage of circulating load). Total load to the first machine in the circuit is S + *tonnage of original feed.* Tonnage in closed roll circuits varies (Table 22) from 1.3 to 5 times the original feed; average, 2.5 times. Proceed as in (1).

13. Rolls *vs.* disk crushers

Smooth-faced rolls are limited in service at the coarse end to 3.5- to 4-in. feed, taking 25° as the allowable angle of nip and 72- to 78-in. as the largest diameter manufactured, and even these rolls are limited to a 2 : 1 reduction

ratio on such feed (see Table 23). The capacity of such rolls is enormous, but so also are the weight, cost and power consumption. A disk crusher, on the other hand, will take coarser feed, if necessary, will make a larger reduction on 3- to 4-in. feed, and, although of smaller capacity than rolls, is of much less weight, cost and power consumption. Hence in the coarse range of intermediate crushing the disk crusher is preferable to rolls, and particularly so in plants of relatively small capacity. In the intermediate range, taking feeds of 2- or 2.5-in. maximum size and making a 4 or 6 : 1 size reduction, both rolls and disk crushers are available. Here the advantage is probably with rolls if the rock is hard and the tonnages large and with disks under the reverse conditions, it being borne in mind that rolls are the more rugged machines and will probably cost less in repairs and delay due to shut-downs. For fine crushing, delivering at, say, ¼-in. or finer, the advantage is all with rolls.

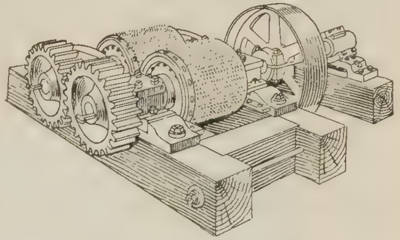

FIG. 44.—Toothed rolls.

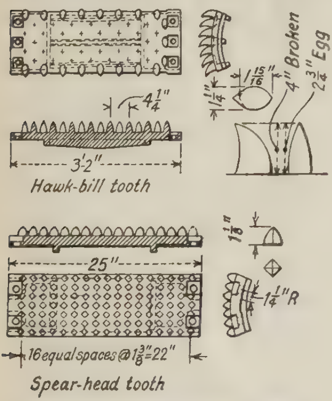

FIG. 45.—Toothed-roll shells (*66 A 422*).

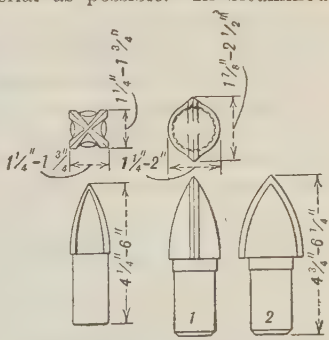
14. Rolls for coal breaking

These are to be considered from an entirely different point of view than the rolls used in rock crushing. The duty required from anthracite rolls is breakage through a relatively coarse screen (rarely less than 1½-in. and usually 3⅜-in. aperture) with as little oversize and as little −¾-in. material as possible. In bituminous work 2½- to 3½-in. is usually as fine as rolls are called upon to crush. The breaking work is relatively easy and toothed rolls are ordinarily used. The reduction ratio is small and the question of nip angle is unimportant, hence the rolls required for a given capacity may be much lighter and smaller than rock-breaking rolls. Fig. 44 is an assembly of a typical set of coal-breaking rolls with toothed shells. The rolls are geared to insure that the teeth mesh properly. The shells are usually cylindrical segments, bolted to the core, and in most modern forms are fitted with replaceable teeth, usually made of manganese steel.



Johnson tooth. Spear-head tooth.

FIG. 46.—Details of roll teeth (*after Ashmead*).

The shape and spacing of the teeth are of the utmost importance in determining the performance of the rolls. Fig. 45

shows two common forms of tooth used in anthracite breakers. Fig. 46 shows details of the usual spearhead tooth for different sizes of rolls and also an improved form of tooth that is claimed to produce a greater percentage of domestic-size coal than the usual forms.

Table 25 gives performances of rolls at a number of anthracite breakers. The tests at Lansford No. 5, which are directly comparable, show a distinct advantage for the Johnson tooth. The tests at Rahn No. 11 are not comparable, but comparison of tests Nos. *31* and *32* at Rahn No. 11 with test No. *35* at Tamaqua No. 14 would seem to indicate, if the coals are not greatly unlike in breaking characteristics, that in breaking from steamboat to egg size the Johnson tooth produces both less fines and less oversize than the usual forms. Tests Nos. *34* and *35* are directly comparable and show a marked advantage in crushing with the Johnson tooth in that it produces no more steam-size coal, in fact a little less, in breaking from steamboat to egg size than the ordinary tooth in breaking from steamboat to broken size. Comparison of tests *6*, *8*, *11*, *14*, *16*, and *18* indicates that in general high peripheral speeds cause higher production of steam sizes than low speeds, but test *18* is not concordant. The tests presented in Fig. 47, as well as the results in Table 25 taken as a

anthracite breakers. (*After Ashmead, 66 A 422*)

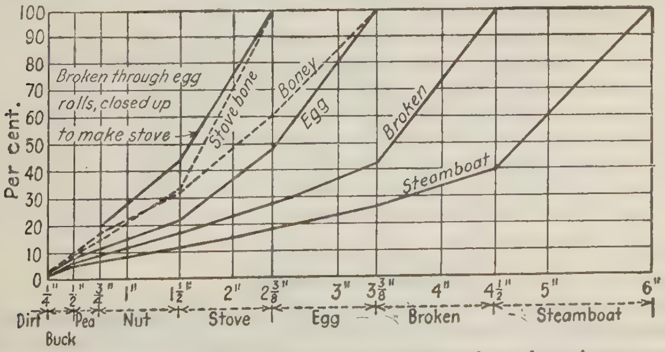

FIG. 47.—Percentages of different sizes in coal broken through various screens by toothed rolls (*after Ashmead*).

whole, show, as is to be expected, that the finer the domestic size crushed to, the greater the percentage of steam sizes.

Test on toothed rolls at CRANBERRY CREEK COAL Co. anthracite breaker (*19 CA 311*): No. 1 rolls, 33-in. diameter with 4-in. Johnson hollow-ground teeth staggered in both directions. Rolls were set 42¾ in. center to center. Speed, 33 r.p.m. No. 2 rolls, same diameter and speed, but teeth were 2¼ in. high and rolls were set 41¼ in. center to center. No. 3 rolls, same diameter and speed, height of teeth the same as in No. 2 rolls but setting was 40¾ in. Feed to the series of rolls was +6-in. lump coal. Flow-sheet was as shown in Fig. 48. Results were as shown in Table 26. Adjustment of the rolls raised the percentage of domestic sizes in the final product from 79.3 to the figure (82.6) given in the table. Lincoln (*11 Bul. UI No. 9*) notes that the product of toothed rolls crushing bituminous coal has substantially the same size distribution as that of coal as broken in mining. Comparative screen tests are given in Table 27.

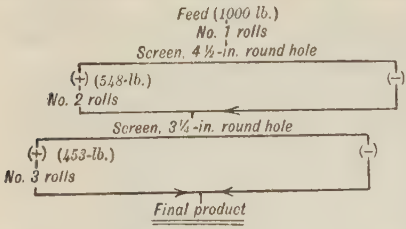

FIG. 48.—Flow-sheet for test on toothed rolls.

15. Single-roll crusher

This machine (Fig. 49) is used for relatively soft materials such as coal, stratified shale, limestone and the like, where a large size reduction is required in one passage. The elements of the machine are the toothed roll (*a*) and

the stationary breaking plate (*b*). The roll is driven by gear (*c*) and pinion (*d*, by means of a belt and drive pulley (*e*). The breaking plate, hinged on (*h*), is held in position by two heavy bolts (*f*), one on each side, with a nest of compression springs (*g*) under the upper nuts to permit the plate to move away when an unbreakable substance is fed. The roll shell is renewable and, in the form shown, has renewable teeth as well. Renewable wearing plates, usually corrugated, are also provided for the fixed breaking plate. Sizes vary from 24 × 48-in. (roll 24-in. diameter by 48-in. long) of 60 to 200 tons capacity per hour, according to the material and setting, to 60 × 84-in. with a rated capacity of 500 to 1500 tons per hr.

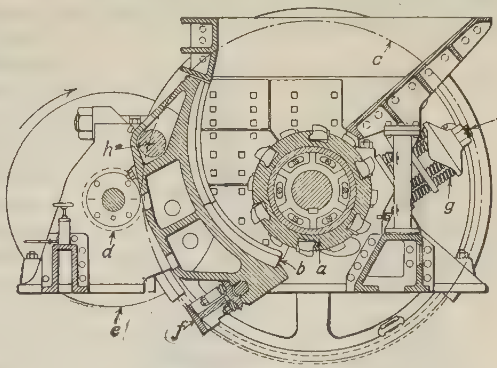

Fig. 49.—Single-roll crusher.

STAMPS

Stamps are a mechanical form of the ancient mortar and pestle. Two types have had long use, *viz.*: the steam stamp and the gravity stamp. A third type, actuated in various ways by crank or eccentric has appeared in many different forms, but has not been widely used. The use of steam stamps has been limited, with the exception of a few experimental installations, to the native-copper mills of the Lake Superior district. Gravity stamps have found their principal field as final grinders of precious-metal ores for amalgamation. They are unexcelled in preparing ores for amalgamation and as machines in which amalgamation can be performed simultaneously with crushing. Sporadic attempts to place them in base-metal mills in the days before flotation failed on account of their slime-producing proclivity. With the introduction of the cyanide process, particularly the all-slime process, finer grinding than could be economically performed in stamps with one pass of the material became necessary and since stamps are unfitted for closed-circuit grinding, and the dilution necessary is bad for cyanide work, tube mills were installed for final grinding and the stamps were relegated to the position of intermediate crushers. In this service they come into competition with more efficient machines such as rolls, disk crushers, and ball and rod mills, and are probably on the way to complete disappearance except in isolated special instances of hard ores and low mill capacities, where their flexibility and ability to make a large size reduction outweigh their disadvantages, or where discard from existing plants would involve greater capital charges than are warranted.

16. Steam stamp

Description. A steam stamp (Fig. 50) consists essentially of a die resting in a mortar (*a*) with perforate walls, and a pestle (*b*) connected at the upper end with a piston rod (*c*) actuated up and down by a piston in a steam cylinder (*d*). The mortar rests on a heavy metal anvil block which in turn rests on an enor-

mous block of concrete. The steam end is carried on a frame (*e*) which is entirely separate from the mortar. The stamp stem is kept in alignment by guides (*f*), with phosphor-bronze boxes, carried on transverse supports attached to the legs of frame (*e*). The steam end may be simple, cross-compound or steeple-compound. The CROSS-COMPOUND is an intermediate form in the development from the old simple form which was recklessly inefficient in steam consumption, to the modern efficient steeple-compound type. Valves, are driven by a cam-and-eccentric mechanism from shaft (*g*) which, in turn, is driven by an independent motor. The cylinder of the simple stamp has become standard at 20-in. diameter by 24-in. length. Simple stamps are operated condensing, taking steam at 115 to 120 lb. per sq. in. and making 105 to 110 strokes per minute. Many are of the LEAVITT TYPE (Fig. 51) with two pistons (*a*) and (*b*) of different diameters. Steam is admitted by means of a griddle slide valve through port (*c*) to the upper side of the larger piston and exhausted through a similar valve and port (*d*) to the condenser. The space (*e*) surrounding the lower cylinder and connecting with its interior through ports (*f*) is a receiver into which steam is admitted under constant pressure, to which pressure the under side of piston (*b*) is subject at all times.

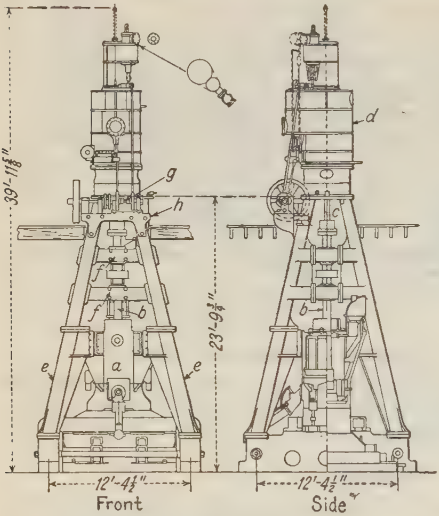

FIG. 50.—Steam stamp.

The lower part of the upper cylinder and upper part of the lower cylinder are at all times connected to the vacuum of the condenser. The constant pressure on the under side of (*b*) is sufficient to lift the stamp, but the pressure on top of (*a*) is greatly in excess of this and makes the force of the blow enormous. The economy of operation of the simple stamp is low because of the large clearance, amounting to as much as 20 per cent., made necessary by reason of the variable thickness of ore on the dies and the wear of shoes and dies. In the STEEPLE-COMPOUND, the high-pressure cylinder is 15½ × 24-in. and the low-pressure cylinder, mounted above in order to facilitate removal of pistons, is 32 × 24-in. A re-heater is installed on the steam line between the high- and low-pressure cylinders. The high-pressure cylinder has four valves, two inlet and two exhaust, each driven by a separate eccentric, the lower or lifting valves from a constant-speed drive shaft, the upper or driving valves from a separate shaft driven from the first at a non-uniform rate through a drag-link mechanism, which permits fast opening and closing. The low-pressure cylinder has two valves only, connecting with the upper side of the

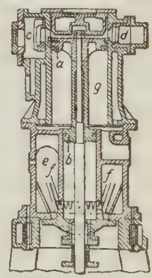

FIG. 51.—Cylinder of Leavitt steam stamp.

piston; the under side of the piston is connected constantly with the condenser, which eliminates considerable clearance. The usual steam pressures are 140 to 160 lb. per sq. in. in the high-pressure cylinder and 35 to 40 in the low.

Recently exhaust steam from the stamps has been used, mixed with boiler steam, if necessary, to run steam turbines. This is a considerable advance in steam economy.

A typical STEM has an oblong detachable shoe and rubber-packed dash-pot connection with the piston rod to prevent breakage of the rod; a swelling or "BONNET" at the top of the stem serves a secondary purpose by striking against a dash-pot buffer in the entablature (*h*) (Fig. 50), when the stamp is lifted too high, and thus preventing the piston from knocking out the upper cylinder head. Similarly it strikes a warning bell when the layer of feed on the die becomes too thin. SHOE is made of chilled cast iron, weighs 750 to 800 lb. new and 300 to 400 lb. when discarded. The life is 4 days to 2 weeks. The complete stamp stem, shoe, piston and piston rod, weighs 5500 to 7900 lb. The lifting velocity is 8 to 10 ft. per sec. and falling velocity 20 to 24 ft. per sec. The striking force of the shoe is of the order of 25 to 50 tons. The MORTAR may be circular or rectangular. The bottom is protected by a false die on which the crushing die rests, centered by a die ring which is wedged in place by sectional side liners; a key or king stave bolted through the mortar locks the whole lining in place. LINERS and DIE are made of chilled cast iron. The die weighs about 800 lb. new and about 500 lb. when discarded. The life is 6 months to 1 year. SCREENS surround 50 to 75 per cent. of the periphery of the mortar above the liners. The usual height of the bottom of the screen above the top of a new die is 9 to 10 in.; with a worn die the height increases to 13 to 16 in. Screens are punched plate with 5⁄16-in. to 5⁄8-in. round openings. One panel is usually covered with screen having 50 per cent. larger apertures than the balance in order to pass copper that is free but cannot escape through either the finer screen or the HYDRAULIC DISCHARGE. The latter, in its simplest form is an inclined pipe-like opening through the mortar wall, up which water is introduced into the mortar at such velocity that only the largest particles of metallic copper can settle against the current. Another form has a small plunger jig, arranged to feed from a slot in the side liner just below the mortar grate. Either type will remove copper between 5⁄8-in. and 4-in. size. Larger lumps must be manually removed; smaller pass the screens. The MORTAR JIG has a 1-in. screen and discharges fine copper from the hutch, coarse copper from the screen and middling over the tail board. The mortar rests on a solid cast-iron ANVIL BLOCK which in turn may rest either on hardwood spring timbers or directly on a concrete foundation slab. The latter is more recent practice; it increases capacity and lessens repair costs.

Operation. Steam stamps are fed by hand through sloping chutes from feed bins containing −4-in. jaw-crusher product. The operator controls the flow by means of a hook or hoe so as to keep the thinnest safe layer of material on the dies. He picks mass copper, wood and mine waste from the feed stream. Water is introduced with the feed and also through the hydraulic discharges. The total amount introduced is from 3 to 7 tons per ton of feed.

Performance. Table 28 gives typical data on simple and compound stamps working on conglomerate and amygdaloid respectively.

The capacity of a simple stamp crushing amygdaloid through 5⁄8-in. screen at QUINCY is 450 to 500 tons per 24 hr. and the capacity of a steeple-compound in the same service at the same plant is 700 to 800 tons. When crushing amygdaloid through 5⁄8-in. screen

about 70 per cent. of the stamp product is less than half the screen aperture in size and 40 per cent. is smaller than 0.1-in. Cost of crushing in steam stamps ranged from $0.15 to $0.30 per ton (1907).

Steam pressure, lb. per sq. in.	148	118

17. Gravity stamp

Description. A gravity-stamp battery is shown in Fig. 52. The essential parts are the frame (A), mortar block (B), mortar (C) containing die (D) on which ore is broken by a pestle composed of shoe (E), boss head (F), stem (G) and tappet (H). The pestle is lifted through the tappet by means of cams

(I) carried on cam shaft (J) driven by pulley (K) and belt (L) from pulley (M) on countershaft (N). Ore to be crushed passes from the bin (O) through the automatic feeder (P) to the mortar and is discharged, when fine enough, through screen (Q). Stamps are rated on the weight of the falling part. The usual weights in American mills are from 1250 to 1500 lb. In South Africa 1500- to 2000-lb. falling weights are more usual. Old California practice was to use 850- to 1050-lb. stamps and many of these are still found.

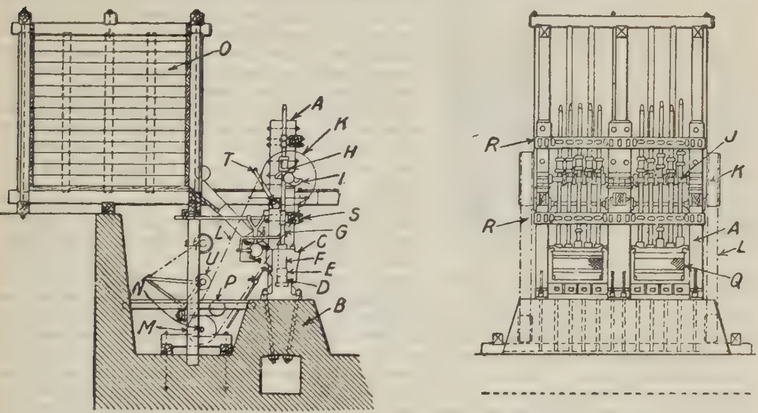

Fig. 52.—Typical 10-stamp battery.

The weight of a complete 5-stamp battery, excluding wood of frame, ranges from 20 times the weight of an individual stamp for batteries under 1000-lb. falling weight to about 15 times for heavy stamps. Of this total the weight of the falling parts and mortar is about 55 to 65 per cent. for stamps under 1000-lb. increasing to 75 to 80 per cent. for the heaviest stamps.

Frames are commonly made of timber, but cast iron, structural iron and reinforced concrete have also been used. Timber frames are made in three forms. The back-knee frame (Fig. 52) is tied to the ore bin directly behind by means of sills and girts as shown. The main posts (A) carry guide timbers (S) which in turn carry guides for directing and confining the up-and-down motion of the stamp. The main sills are tied together by cross sills and rest on mud sills. Finger bars (T) resting on a jack shaft are arranged to slide under the tappets and hold them stationary above the reach of the cams. The front-knee frame differs from the back-knee frame in that a horizontal member for supporting the drive shaft is framed in front of the main timbers at about the level of the cam shaft and is supported on the outer end by posts; the frame is further stiffened by means of diagonal members running from these posts to the top of the main posts. The front-knee frame allows horizontal drive and does away with the use of the tightener (U, Fig. 52) that is necessary when the drive countershaft is placed on the sills, but unless individual drive is used a clutch pulley is required on the driving shaft to permit an individual battery to be thrown out. The A-frame is stiffened entirely by an inclined post in front. This frame is the least rigid of the three and the least used. The drive countershaft is placed on the main sills either in front of or behind the posts and a belt tightener must be used. The front-knee frame gives the most floor space and easy access to the cams but is expensive and obstructs light.

Main posts are commonly 12 × 24-in. or 12 × 26-in.; sills and girts 10 × 12-in. or 12 × 12-in., and guide timbers 12 × 12-in. and 12 × 14-in.

When 10 stamps are carried on the same cam shaft, as is usual, common practice is to carry one center cam-shaft bearing on a single central post and to drive from one end. Cam shafts will vibrate less and last longer if a 4-post frame is used with the bull wheel placed between the two central posts. At Suan, Korea (*119 P 916*), shafts broke frequently, even with this arrangement. The difficulty was overcome by cutting the shafts at the center, placing the two driving pulleys side by side and driving both with the same belt. Pulley faces were turned to bring a common crown at the center.

Drive is usually from a countershaft, belt-driven from one large motor, but the latest practice is to use a back-geared motor belted directly to each 5- or 10-stamp battery. The greater initial cost of the unit installation is considered to be more than overbalanced by its greater flexibility and convenience and by elimination of the difficulty of maintaining alignment of the long countershaft. At AURORA, Nev. (*99 J 97*), the motor is sufficiently powerful to start the stamps from any position so that it is not necessary to hang up.

Mortar block should be as rigid as possible in order to obtain the maximum crushing effect. The old practice was to use wood; modern blocks are almost invariably concrete. They are more rigid, more easily built and have much longer life; stamps set on them have greater capacity than those set on wood. They should be footed on rock, if possible, but if rock cannot be reached at less than 16 to 18 ft., they may be footed safely on gravel or firm soil, if given a broad base. In any case the block should have a generous batter, at least 30° from the vertical; the ends are extended at the proper height for the main sills and where more than ten stamps are installed it is the usual practice to make the blocks continuous below the sills. Details of typical concrete mortar blocks are shown in Fig. 53. Bolts should never be cast into a concrete block on account of the difficulty of replacing them when broken. The form with bolts coming to the outside gives trouble with heavy stamps because of the difficulty of casting the projections (*97 J 664*). A good mixture for a concrete block is 4 of 2½-in. rock, 2 of sand and 1 of cement. The top 6 or 8 in. should be made somewhat richer than this to prevent cracking.

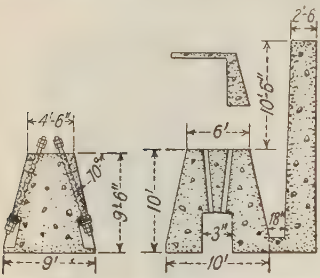

FIG. 53.—Concrete mortar block.

Anvil block is a heavy cast-iron sub-base sometimes used between the mortar and a wooden mortar block. With a wooden foundation it increases stamp capacity and lessens vibration but RAND experience is summed up by Bosqui (*52 A 24*) in the statement that its use caused excessive stem and cam-shaft breakage. Caldecott (*19 IMM 57* [*1909-10*]) gives a stamp duty of 6.84 tons with a heavy cast-iron anvil on a wooden block, against 6.78 tons with the mortar directly on concrete, with 26.75 and 25 per cent. of +0.01-in. material in the products, respectively.

Mortar is usually set on the mortar block on a pad of rubber or hair felt ¼ in. to ⅜ in. thick, and bolted down by 6 or 8 bolts of 1½- to 2¼-in. diameter. Since the use of concrete mortar blocks has become general many designers omit the pad. Mortars commonly hold five dies. A typical mortar is shown in Fig. 54. Variation in detail of mortars depends upon the purpose for which they are to be used and upon the kind of mortar block. The weight of the mortar varies with the weight of the stamps, ranging from 6 times the falling weight with light stamps to 9 or 10 times with heavy stamps. The narrow, straight-backed mortar shown in Fig. 54 is designed for rapid discharge and high capacity. It is cast roughly as a deep box with feed opening (*A*) at the back and discharge opening at the front. The bottom is planed to give an even bearing. The base is broad on mortars meant for concrete mortar blocks and narrow for wooden blocks. The screen (*C*) is held in the discharge opening by means of wedges (*D*) which press the screen frame tightly against planed surfaces on the mortar. Chuck blocks (*E*), held in place by wedges, are inserted for the purpose of varying the height of the screen. Where amalgamation is practiced it is usual to mount a copper amalgamating plate (*F*) on the chuck block in order to catch some gold in the battery. A wooden cover (*G*) to prevent splash rests on a shelf cast on the walls of the mortar. It is provided with holes for the stamp stems. Liner plates (*H*) in the feed chute, sides and ends protect the casting from wear and are easily replaceable. Amalgamating mortars are wider and are provided with a rear amalgamating plate as well as a chuck-block plate; provision is made by means of a removable cover for access to the back plate without lifting the stamps. Crushing is not so rapid as in the narrow mortar; such a mortar is used when amalgamation in the battery is more important than rapid crushing. DOUBLE-DISCHARGE MORTARS arranged with screens front and rear, with provision for conducting pulp discharged at the rear through the mortar base to join pulp discharged at the front, were devised to increase the crushing rate. Caldecott (*19 IMM 57*) showed substantially identical duty for 1350-lb. stamps working in single- and double-discharge mortars on RAND

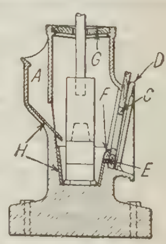

FIG. 54. — Narrow straight-backed mortar (Homestake type) with broad base for concrete mortar block.

ores, 5.8 tons through 0.024-in. screen in both cases. The double-discharge mortar had 3¾-in. discharge height against 2¾-in. in the single-discharge mortar, it used 10.7 tons of water per ton to 7.7 in the single-discharge and with a feed containing 3 per cent. more − ¾-in. material, the product contained 3 per cent. less +0.01-in. sand. A so-called OPEN-FRONT MORTAR is made, with removable front, making for ease in removing shoes, boss and stems.

The mortar is made of tough, gray cast iron. The feed opening usually extends the length of the three center stamps but in some mortars is made full length. Feed is supplied in a narrow stream at the center and is distributed by the swash of pulp. The choice of a mortar is influenced not only by capacity requirements but also by considerations of recovery of precious metals. The design of a mortar has a considerable influence on operation and there is little adjustment possible. It is therefore important that the proper choice be made in the first instance. With ores containing minute particles of rusty gold which require burnishing before amalgamation can be accomplished, fine grinding is necessary and a wide mortar with back and front plates and a fine screen should be used, if the battery is dependend upon for all of the crushing. With a free-milling ore containing coarse gold that is easily separated from the gangue, a narrow, single-discharge mortar is properly used. This mortar should also be used where the purpose is high capacity, and later machines are depended upon for completion of the grinding. The limit of narrowness is imposed by the requirement of a space between the dies and front and back walls greater than that of the largest particles of feed in order to prevent wedging therein with consequent strain on the stem. For maximum capacity with minimum stem breakage the back should be about 2½ in. from the back of the dies and the screen about 5½ in. from the front of the dies. The slope of the back is set at about 75° from horizontal and the screen at 75° to 80°.

King (*11 MM 378*) reports that at a plant in WESTERN AUSTRALIA when cyaniding replaced amalgamation, the old wide mortars were narrowed by steel-plate liners backed with hardwood, with resulting duties for 1050-lb. stamps on a quartz ore containing 50 to 60 per cent. granite of 4.8 tons through 30-mesh, 6.3 tons through 20-mesh and 8.9 tons through 10-mesh. These figures represented increases of 50 per cent. over those obtained with the wide amalgamating mortars.

Mortar liners were not used in the majority of mills when fine crushing was practiced, but the mortar was made sufficiently heavy to last 3 to 6 years. The average life of 5500-lb. mortars at HOMESTAKE (4.5-ton stamp duty) was 3 years. Recent practice in high-duty coarse-crushing batteries is to use both end and side liners. At NIPISSING (*48 A 13*) chilled cast-iron liners 1 in. thick lasted 30 days; manganese steel lasted 165 days. At SUAN (*119 P 916*) back liners are made in upper and lower sections, since the upper part wears much more quickly than the lower. At BELMONT-SHAWMUT (*121 P 659*) cast-iron front liners 1 in. thick last 4 months, back liners ¼ in. thick and end liners 1 in. thick last 6 months.

Some mortars are provided with lugs for holding a SPLASH BOARD in front of the screen. This is particularly necessary where the pulp is thin and a coarse screen is used. An amalgamating plate is sometimes attached to the splash board.

Sectional mortars are made for shipment into inaccessible regions. The mortar is divided into sections transversely and each joint is faced and grooved in order to make a water-tight and mercury-tight joint. The whole is tied together by means of tie bolts that fit into reamed holes. The top is made of steel plate riveted together or of hardwood back and front bolted against cast-iron ends. Riveted joints tend to loosen. Hardwood can be tightened up from time to time by taking up on the bolts. The sections are made so that no piece much exceeds 300 lb. weight. Stems are made somewhat lighter than standard to go with sectional mortars and a hollow cam shaft is likewise furnished.

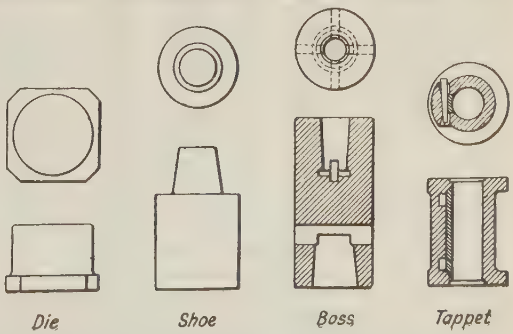

FIG. 55.—Stamp parts.

Dies (Fig. 55) are inserted in the bottom of the mortar. They are subject to hard wear and are therefore made of special wear-resisting material. Chilled cast iron, semi-steel, forged steel, chrome steel and manganese steel are the usual metals employed. Normally the shoe and die are made of the same material but some

operators have reported good results with cast-iron or semi-steel dies working against forged- or chrome-steel shoes. The die shown is the ordinary form with square base and clipped corner to permit the insertion of a bar to pry the die out of the mortar. Dimensions and weights of dies for different weights of stamps are given in Table 30.

a Taken complete from Power & Mining Machinery Co., Bull. 41. Dimensions and weights of standard equipment of other makers differ slightly but not essentially. Compare Table 31, from practice.

It is good practice to replace dies before they are worn to full depth, for the reason that the surface becomes very irregular with wear and that crushing efficiency is thereby lost. By making dies ¼ in. larger than the shoes, contact of the shoe with the die over the whole face of the shoe is insured even after considerable stem and die wear. This

makes for more even wear of shoes and dies and higher crushing duty. In order to save in amount of metal thus wasted, a sectional die with replaceable face is sometimes used. At SUAN, Korea (*119 P 916*), half-worn shoes are used for the upper part of sectional dies; this practice has an incidental advantage that there is less variation in height of discharge between new and worn-out dies than is the case with solid dies. The average life for solid dies on ordinary ores is about 60 days (Table 31). Three-year average for hard cast-iron

dies at HOMESTAKE (900-lb. stamps) was 30 to 35 days (*22 IMM 74*). At NIPISSING (*48 A 13*) forged chrome-steel dies lasted 130 days with very hard tough ore; at SUAN (*119 P 916*) the same material lasts 100 to 120 days. At CHURCHILL WONDER (*52 A 128*) the consumption of forged chrome-steel dies on hard tough quartz was 0.107 lb. per ton crushed through ⅜-in. screen. At RAINBOW chrome-steel dies last 100 to 120 days with 1050-lb. stamps crushing through 4-mesh. Consumption of cast-iron dies at ALASKA

Treadwell (*102 J 63*) was 0.17 to 0.24 lb. per ton crushed. At Zaruma, Ecuador (*111 J 583*), the consumption of chrome-steel dies was 0.12 lb. per ton.

Dies are ordinarily set in the mortar without fastening, but at one plant dies were grouted into place with a mixture of 2 cement and 3 sand up to the level of the chuck block; notwithstanding that several days were required for the cement to set, increased duty, due to the time saved in battery clean-up and increased crushing rate counterbalanced the lost time; further advantages claimed are better inside amalgamation due to the fact that amalgam and quicksilver are kept up near the inside plates; smaller amount of battery sand to clean up; no necessity to remove dies at clean-up time; rigidity of dies. The concrete wears with the dies and is mostly gone when the latter are worn out, so that they are not hard to remove.

Shoe (Fig. 55) is the lowest part of the stamp and is subjected to great wear. Shoes are therefore made replaceable and of wear-resisting material such as cast iron, chilled iron, cast steel, forged steel, chromium or manganese steel. Common practice is to use forged or alloy steel. The question of economy depends upon the first cost and the extent to which the shoes can be worn down. With a local foundry and high freight cost, the choice between cast shoes and shoes of special steel may be a close one. At Waihi, N. Z. (*16 Aa 124*), local cast-steel dies showed 50 per cent. economy over imported forged steel but forged-steel shoes were used. The liability of cast shoes to breakage, and the cost of replacement must be borne in mind in making any decision in favor of the cast product. Dixon (*18 JCM 240*) cites a mill record showing 10.9 per cent. shank breakage with cast shoes against 3.5 per cent. with forged. Castings containing more than 1 per cent. carbon are most likely to break. At Passagem (*20 IMM 16*) the life of locally cast shoes and dies was about half that of imported forged steel.

The shank of the shoe fits loosely into a cored recess in the bottom of the boss head and is wedged in by means of hardwood wedges which swell when wet and make a firm joint. In dry crushing steel wedges are used. Weights and dimensions of shoes for various weights of stamps are given in Table 30.

Wear of shoes varies considerably with the character of ore and kind of material. An average life of from 60 to 90 days for forged- or chrome-steel shoes working on medium ores is a fair figure. The three-year average for chilled cast-iron shoes on 900-lb. stamps at Homestake was 60 to 90 days (*22 IMM 74*). Forged chrome-steel shoes at Nipissing lasted 105 days (*48 A 13*) and 100 to 120 days at Suan (*119 P 916*). Consumption of the same material at Churchill-Wonder (*52 A 128*) crushing hard tough quartz through ⅜-in. screen was 0.232 lb. per ton. At Rainbow (*99 J 1104*) the life of chrome-steel shoes was 80 to 90 days with 1050-lb. stamps and 4-mesh screen. Consumption of chrome-steel shoes at Alaska Treadwell (*102 J 46*) was 0.37 to 0.41 lb. per ton of ore crushed. At Zaruma (*111 J 583*) the consumption of chrome-steel shoes was 0.29 lb. per ton. Table 31 gives detailed data on wear at various mills. According to Wraight (*30 IMM 201*) the figures in Table 32 are average for wear of shoes and dies of different materials. He recommends specifications as given in Table 33. Del Mar (*40 MEW 687*) records the failure of

manganese-steel shoes by deep chipping. Foote (*122 P 739*) states that at North Star two sets of five shoes all failed by casting a flat disk 1 to 3 in. thick and the diameter of the shoe. Loring (*28 A 553*) gives a life of 296 days for manganese-steel shoes working against cast-iron dies (life 120 days) at Utica mills with 5-ton stamp duty. Alloy-steel shoes and dies with exceptionally slow wear may not be economical, if the wear results in uneven crushing surfaces, because of the resulting loss in crushing duty.

Boss head, sometimes called boss or head, is shown in Fig. 55. It forms a link between stem and shoe and also adds materially to the falling weight of the stamp. It is made of cast iron, cast steel, or chrome steel, cored out at the bottom to receive the shank of the shoe and bored to a taper at the top for receiving the tapered end of the stem. Slots are cored at right angles at the bottom of the tapered openings to receive drift keys for driving out the stem and shoe. Weights and dimensions of boss heads for various weights of stamps are given in Table 30. Cast-iron boss heads are sometimes reinforced with wrought-iron bands, shrunk on, to prevent cracking. This was particularly necessary in dry crushing practice when steel wedges were used for holding on the shoe. The stem is likely, also, to split cast-iron boss heads. Life is indefinitely long and is terminated by breakage. Figures reported by mills are 330 days; 400 to 600 days; 4 years; five boss heads for 40 stamps in 14 years. Homestake average for cast-iron bosses with 900-lb. stamps is 6 years (*22 IMM 74*). At Suan (*119 P 916*) chrome-steel bosses on 1050-lb. stamps last 2 to 4 years.

Stems are made of hammered iron or mild steel, turned and polished and tapered both ends so as to make them reversible in case of breakage. Wraight (*30 IMM 201*) recommends a steel analyzing: C, 0.15 to 0.25 per cent.; Si, up to 0.15 per cent.; S + P, 0.06 per cent. max.; Mn, up to 0.6 per cent. Dimensions for stamps of different weights are given in Table 30.

The amount of breakage depends upon the length, the location and condition of guides, and the weight of the tappet. Long stems with heavy tappets and worn guides break in a short time while under reverse conditions breakage is almost unknown. Steel and occasional large lumps in the feed cause eccentric strains that produce much breakage. The break usually occurs near the boss. Broken stems are turned end-for-end. Broken ends may be turned down and the stem again used, if not too short. Annealing before turning down will defer subsequent breakage. In starting, the center stamp should be started first to save pounding on empty dies with consequent stem breakage. Average life at Homestake over a 3-year period for wrought-iron stems 3⅛-in. diameter was 4 months. Mild-steel stems 3$\frac{7}{16}$-in. diameter at Suan, Korea (*119 P 916*) on 1050-lb. stamps last 4 years.

Tappets (Fig. 55) are made of cast iron, cast steel, or alloy steel. The purpose of the tappet is to convert the rotary motion of the cam-shaft into rectilinear motion of the stamp. Tappets are cast with a cored opening which is bored out to fit the stem. A recess in the opening receives a steel gib that is bored out with the tappet. The gib is pressed against the stem by keys driven through the keyways shown. Some makers counterbore the hole through the tappet slightly off the center of the original bore in order to give a three-line bearing of the tappet on the stem when the gib is tightened. Tappets are faced both ends and counterbored to a width slightly less than the face of the cams in order to prevent shouldering and consequent side thrust Both ends of the tappet are alike and it is therefore reversible. Two or three keys are used. Three-key tappets should be used on heavy stamps and are less likely to slip in any case, but are somewhat more trouble to set up. Dimensions and weights of tappets for various weights of stamps are given in Table 30. Life is indefinite. Figures reported are: 320 days; 650 days; about 4 years; 100 tappets in 14 years for 40 stamps, first 40 tappets of chrome steel broke in a short time. Chrome-steel tappets at Suan (*119 P 916*) last 2 to 4 years. At Homestake cast-iron tappets averaged upward of 600 days life (*22 IMM 74*).

Compensating weights are split rings weighing 20 to 40 lb. each, made to bolt around the stem either just above the boss or above the tappet. Without their use the falling weight with a worn shoe and a short stem may be as much as 10 per cent. less than the new weight and there will be an accompanying decrease in stamp duty. They are best placed at the boss; at the tappet they increase vibration and stem breakage.

Cams, mounted on a shaft, working against the tappets, lift and drop the stamps. Cams are made two-armed and are ordinarily designed to lift the stamps at constant speed; the cam surface is, therefore, the involute of a circle, somewhat flattened, however, at the two ends. Another form, designed for constant acceleration of the rising stamp was used at North Star. Cams are made of cast iron with chilled faces or of cast or special steels. The best material should be used in order to get strength without clumsiness and undue weight. At Homestake (*114 J 761*) chrome adamantine steel is used for cams with 10-in. drop and cast iron for 8- to 8.5-in. drop. Cams are designed for a short drop (6 to 8 in.) or for a long drop (14 to 16 in.) according to the particular practice for which they are desired. It is important that the cam be closely designed for the required drop length. The design should be such that the vertical tangent to the inscribing circle passes

through the point of contact of the cam with the tappet, or the radius of the inscribing circle should equal the distance between cam-shaft and stem centers. If the stroke length is greatly shortened without changing cams, the stamps are picked up at a point on the cam face that is moving with excessive velocity, with the result of much noise and undue strain on the cam, cam-shaft and tappet fastenings.

Cams were keyed to the shaft in the older mills but present practice is to use a special form of fastener so designed that the load on the cam tends to tighten it on the shaft, while it may be easily loosened by a blow in the reverse direction. Two forms of such fasteners are shown in Fig. 56. Fastener (*A*), known as the Blanton, consists of a curved wedge (*a*) with two pins (*b*) that fit into holes drilled in the shaft. The cam is bored eccentrically to slip over this wedge and tighten thereon when turned on the shaft in the direction opposite to the direction of rotation. This is the fastener most commonly used. The Davis fastener (Fig. 56, *B*), has a lozenge-shaped piece (*c*) that fits into a correspondingly shaped depression in the shaft. A channel is cut in the cam to allow it to slide over the lozenge. Eccentric channels are also cut on the inner face of the cam bore in such a way that when the cam turns on the shaft in a direction opposite to the direction of rotation thereof, it wedges tightly. These special fasteners require less metal to be cut out of the cam-shaft than must be taken for a keyway and therefore weaken the shaft less. Cracks are likely to start from the holes drilled for Blanton fasteners and from keyway corners. Fasteners that do not require sharp-edged cuts in the shaft are best. Cams are made right-hand and left-hand. A RIGHT-HAND CAM has the hub projecting toward the right when the cam stands before the observer in a position such that rotation would carry the upper ear away from the observer; a LEFT-HAND CAM has the hub projection toward the left when standing in like position. The shape of the cam face depends upon the height to which the cam is lifted and the necessary distance between the center of the stem and the center of the cam-shaft.

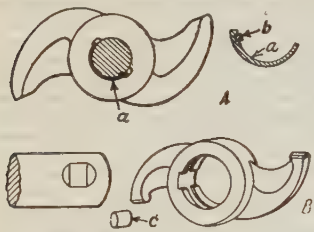

FIG. 56.—Cam fasteners.

Life of cams is indefinite. Figures reported are 500 days; 700 days; 6 months to 3 years; 4 years. Average for cast iron at HOMESTAKE with 900-lb. stamps was upward of 2 years (*22 IMM 74*). Breakage is normally due to CAMMING, *i.e.*, pick-up of the tappet by the cam before the stamp has completed its fall. This is caused by too long stroke or too many strokes per minute.

Height of drop may be varied within small limits, with a given cam, by changing the position of the tappet on the stem. The amount of variation is, however, small, if the tappet is to be picked up at the place on the face of the cam designed for this service. As dies and shoes wear, the height of drop is kept as nearly constant as possible by changing the position of the tappet on the stem to compensate for wear. A skilful operator can make this change while the stamp is in operation by loosening the tappet keys slightly and allowing the upward blow of the cam to slide the tappet on the shaft but this may result in cutting the stem or gib and it is best to hang up the stamp when a change in height of drop is to be made. In general, the height of drop of the stamp in front of the feeder, usually the center stamp, is made about 1 inch greater than that of the others on account of the greater depth of ore at that point. The height of drop of the end stamps is likewise normally made somewhat greater than that of the adjacent stamps in order to overcome the tendency for the ore to pile up in the ends of the mortar.

This arrangement is, however, sometimes varied, thus at SUAN, Korea (*119 P 916*), the center stamp has 9-in. drop; stamps 2 and 4, 8¾-in. and the end stamps, 8½-in.

Drop sequence. Cams are spaced at equal intervals on the cam shaft, 36° or 72° apart, depending upon whether the shaft carries 10 or 5 cams, in order to equalize the load. The sequence in which the stamps in an individual mortar drop has a marked effect on performance. If, numbering the stamps from the pulley end, the drop sequence is 1, 2, 3, 4, 5, ore will be piled up under No. 5

stamp. This will decrease the height of drop and, consequently, the crushing effect and thus will result in more heaping up and eventual stoppage of this stamp. Clogging will then progress along the battery until the latter is completely clogged. Reasoning from this fact, the following rules governing sequence have been set down: (1) No two adjacent stamps should fall in succession. (2) When one stamp is falling its neighbor should be rising. The common sequences, aimed to satisfy this rule, are the HOMESTAKE, **1, 3, 5, 2, 4**, which, stated backward is **1, 4, 2, 5, 3**; CALIFORNIA, **1, 4, 2, 3, 5** = **1, 5, 2, 4, 3**; and modifications of the latter such as **1, 5, 3, 4, 2**; and **1, 5, 3, 2, 4**. The sequence **1, 3, 5, 2, 4** comes nearest to satisfying the theoretical requirements, but many operators claim that the California sequence gives better distribution of pulp on the dies and a swash of pulp in the battery that is better fitted to cause material to pass through the screen.

Clark and Sharwood (*22 IMM 73*) report that at HOMESTAKE the sequence 1, 3, 5, 2, 4 gave slightly greater tonnage than 1, 5, 3, 2, 4. At the GOLD CROSS mill (*88 J 1034* [*1909*]) the drop 1, 4, 2, 3, 5 gave good results while change to the drop 1, 3, 5, 2, 4 caused immediate trouble. The probability is that both drops can be made to work equally well by proper adjustment of the height of drop of individual stamps.

When a 10-stamp battery is used the sequence 1, 3, 5, 2, 4 becomes **1, 7, 3, 9, 5, 2, 8, 4, 10, 6** and 1, 5, 2, 4, 3 becomes **1, 6, 5, 10, 2, 7, 4, 9, 3, 8**.

Cam-shaft is made of a diameter sufficient to withstand the bending stresses imposed by the weight of the cams and the lifting shocks, when supported over a span equal to the distance between the main posts of the frame. It is made of a metal that will withstand the tendency to crystallization brought about by repeated shocks. Mild steel or iron, hammered out and turned to the desired diameter, are the usual metals. Foote (*122 P 739*) says that in operating 1050-lb. stamps at 110 drops per min. 11 shafts were broken by 40 stamps in one year. Forged wrought iron was superior to chrome-nickel steel, vanadium steel, mild or machinery steel, or "Flyer iron." The cam-shaft varies from 5- to 8-in. diameter according to the weight of stamps. At SONS OF GWALIA mine, W. A. (*101 J 224*), a 5½-in. shaft designed for 1000-lb. stamps broke frequently when the falling weight was increased to 1225 lb. Shafts are made to serve batteries of 5 or 10 stamps, never more. The shaft is keyed at one end for a pulley and runs in open boxes. Cam-shafts are designated as right-hand and left-hand, but the terminology is not universal in this respect. A logical method of designation is that in which, when the cams on the shaft are looked at in such a way that the upper ears are moving away from the observer, if the pulley is at the right end of the shaft, the shaft is a RIGHT-HAND SHAFT; if at the left end, a LEFT-HAND SHAFT.

Life of cam-shafts is reported as from 6 months to 5 years. One mill reports 6 months as the average for good shafts and less for poor ones, but this is a poor record. The average for wrought-iron shafts 5.36-in. diameter with 900-lb. stamps at HOMESTAKE was 4 years. Damping shafts by means of wooden blocks pressed down on the shaft over the boxes with a force of 600 to 1000 lb. lengthens the life (*98 J 743*). Broken shafts can be repaired by thermit welding, but must be dismounted for the job (*110 J 1092*) and one or more extra shafts should be kept on hand to reduce delays.

Cam-shaft boxes are made of cast iron or steel bored out to fit the shaft and machined plane on back and bottom. Some makers babbitt the boxes but this is not common practice; broken babbitt may fall into the mortar and contaminate the amalgam. The boxes are half boxes, cast with rims around the base to form an oil reservoir and thus prevent lubricant from dropping into the battery and interfering with amalgamation; canvas covers are frequently used to keep out grit. At some African mills using heavy stamps, bearings were placed on both sides of all cams, the boxes being carried on heavy castings, but alignment was difficult and the castings broke so frequently that the construction was found uneconomical.

Pulley is subjected to heavy service and experience has shown that this service is best withstood by a built-up wooden pulley. A common form consists of a cast-iron flanged hub faced and keyed inside and out, and a movable flange bored to fit the outside of the hub and provided with a key-seat corresponding to that in the outside of the hub. Between these two flanges the pulley is built up of 2-in. plank laid up in linseed oil and white lead, and faced with ⅞-in. plank, all securely bolted together, the flanges bolted through, and the whole turned true and balanced as accurately as possible. Cast-iron pulleys will not stand the strain. Pulleys are finished 7- to 8-ft. diameter by 16- to 20-in. face. The flange is normally 36- to 42-in. diameter for such pulleys. Slipping of the pulley on the shaft gives

considerable trouble in some cases. At HOLLINGER a cast-steel flange was pressed onto the cam shaft with hydraulic jack to overcome trouble from slipping.

Belt tightener must be used when the driving countershaft is placed on the sills. Two forms of tightener are in common use. RACK-AND-PINION TIGHTENER has a tightening pulley carried on a sliding frame that may be racked backward and forward by means of a pinion and hand wheel. SUSPENDED TIGHTENER has the tightening pulley on one end of a lever. The other end of the lever carries a chain that may be wound around a drum fitted with a handwheel. (See Fig. 52.)

Guides are used to hold stems in place and in alignment. They are fastened to guide timbers (S) (Fig. 52). The commonest form is made of maple or other hard wood (Fig. 57). The two halves are bolted together with shims between and bored out to the size of the stems. The shims are planed down as the guides wear, in order to maintain a snug fit against the stems and prevent vibration. Oak guides at HOMESTAKE lasted about 18 months with 850-lb. stamps; hard pine, 4 months. Guide bolts loosen quickly in wooden guides under the vibration to which the battery frame is subjected and there is a considerable amount of friction. Another disadvantage of the ordinary wooden guide is that when a stamp stem is to be removed it is necessary to remove the entire front half of the guide, which necessitates taking out a considerable number of bolts. IRON GUIDES and SECTIONAL WOODEN GUIDES, made to permit removal from one stamp at a time, have been introduced to overcome the various disadvantages of the wooden guides outlined above. With sectional guides it is possible to remove a stem by the removal of two bolts only, and individual adjustment of guides to compensate for the different wear of individual stems is possible. Clark and Sharwood (*22 IMM 73*) report that at HOMESTAKE cast-iron guides reduced friction and renewal cost as compared with maple or oak. Several forms of iron guides have been put on the market; in a typical one solid iron cylinders are bolted individually to a back plate by means of two bolts. The back plate is cast with a bottom rail for insuring alignment of the guides horizontally and bolt holes are carefully drilled to insure vertical alignment. The IDEAL GUIDE has split boxes which are tapered downward and dropped into converging sockets in a cross casting. These may be removed without removing any bolt and are theoretically self-tightening. It is not unknown, however, for them to be lifted by the stem, thereby permitting excessive play and vibration. After iron guides have been polished there is considerably less friction between them and the stems than with wooden guides. The Ideal guide has the sectional advantage likewise. Sectional guides are also made as individual half-boxes for bolting individually onto guide timbers. There is, however, considerable difficulty in getting them into alignment and keeping them there. Another form of iron guide has bushings locked into frames by gib and key. This does away with dependence on bolts and nuts which tend to loosen by reason of the vibration of the frame, but is less easy to handle. Cast-iron guides without babbitt or bushing have the serious disadvantage that they wear the stems badly and that vibration of the worn stems causes excessive stem breakage. Babbitt or bronze bushings obviate this difficulty, but, if battery amalgamation is practiced, the amalgam is frequently badly contaminated by cuttings from the guide liners. The lower guides should be placed as near the boss head and the upper as near the tappets as possible to lessen vibration and stem breakage.

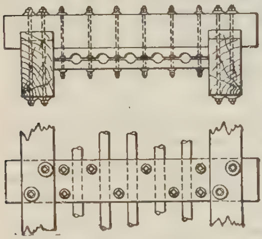

FIG. 57.—Wooden guides.

Finger bars are used to hang up stamps while the cam-shaft is in motion, in order that one or more stamps in the battery may be shut down while others are operating and also in order that the cam-shaft may be started up with no load but friction and the inertia of the shaft to overcome. They are made of hardwood with a leather-lined cast-iron shoe on one end bored out to fit a jack shaft carried between the posts, and at the other end a piece of iron to take the blow of the falling cam. A handle is provided for moving them. A cam stick, consisting of a long acute iron wedge tapering from 1 in. to ½ in. in 18 in. or thereabouts, and flexibly fastened to a handle, is used for getting the tappets on and off the cams. The procedure for lifting a tappet onto the finger bars is to lay the cam stick on top of a rising cam in such a way as to bring it between the surface of the cam and the under surface of the tappet and, as the tappet is raised the additional height, to push the corresponding finger bar forward against the stem so that when the stamp falls the tappet comes to rest on top of the finger bar and out of reach of the revolving cam. To drop the tappet the procedure is similar except that as the tappet is raised by reason of the presence of the cam stick between the cam face and the tappet, the finger bar is removed, allowing the stamp to fall. The handle should be offset in order to keep the fingers of the operators from being caught between the cam and the finger bar.

Screens for the mortar are made up by tacking woven wire or punched plate to heavy wooden frames. Panel pieces are used, if necessary, to prevent excessive bulging of the screen surface. Screens are subjected to considerable wear and the life depends upon the hardness of the ore, acidity of water, material of which the screen is made, type of screen, style of perforation, etc. Discharge through the screen is dependent upon the type of perforation, percentage of opening, and size of opening. The old practice was to use punched tinned plate with circular apertures. This plate is thin, quick-discharging and cheap. If heavy enough to withstand breakage, it is probably the best available, but with narrow, high-discharge mortars failure by breakage is excessive. For heavier service slotted punched plate is used. Present practice, where high capacity with coarse discharge is sought, is to use woven wire, which has a greater percentage of opening (see Sec. 5, Art 3). Brass, copper, bronze and steel are the materials commonly used. Tinned-iron screens are annealed before using by heating them to redness and cooling slowly. Steel wears best but fails quickly with acid water. Screens for fine-crushing stamps are ordinarily renewed before failure on account of the increase in size of aperture through wear, therefore for such crushing heavy plate and heavy wire are not particularly economical, especially in view of the fact that the use of large wire or thick plate reduces capacity by reducing the area of opening. Coarse-wire and heavy-plate screens also are subject to more clogging than lighter screens. Capacity requirements dictate screens of moderate weight even though such practice involves more frequent replacement. Percentage of opening is about the same for medium-weight wire-cloth screens, irrespective of aperture. It is greater for fine cloth than for fine punched plate, but punched plate is stronger. Round holes in plates strain the plate worse than slots and clog more by reason of the fact that they offer three bearing places to grains that attempt to pass. Slotted screens pass a more uneven product than round-hole screens but are preferable for flaky ores. Theoretically, diagonal or horizontal slots should give the freest discharge but swash in the battery modifies this. Punched plate has a burr that should be placed inside. Slotted screens are commonly designated by the needle sizes or the woven-wire meshes to which they correspond.

At Suan, Korea (*119 P 916*), screen with 0.04-in. aperture is used on the lower half of the screen frame and 0.035-in. aperture above.

Life of screens is extremely variable. It ranges from 2 or 3 days to perhaps 2 weeks for fine screens and from 2 weeks to 2 months for coarse screens.

At Homestake (*22 IMM 74*) cold-rolled re-annealed open-hearth steel with diagonal needle slots 0.035 in. wide averaged 10 to 16 days' life and failed by breaking due to wood in the mortar. High-carbon cast crucible-steel wire cloth at Nipissing, 0.25- and 0.4-in. aperture, showed practically no wear after 3 months' service (*48 A 13*).

Prospecting mills. Most manufacturers make one-stamp, two-stamp, three-stamp and five-stamp prospecting mills with stamps ranging in weight from 250 to 450 lb., sectionalized so that no piece exceeds 300 to 350 lb. weight. Such mills require from 2-hp. to 6-hp. engines with boiler rated at 25 to 33 per cent. in excess of the engine. The boiler will weigh so much more than any part of the stamp that much of the advantage of sectionalizing is lost.

Performance of gravity stamps at a number of mills is given in Table 34.

18. Operation of gravity stamps

Duty is the tons crushed per stamp per 24 hr. It varies, according to Table 34, from 1.8 for a 750-lb. stamp crushing through 0.022-in. screen to 21.1 for a 1550-lb. stamp crushing through 0.2- to 0.28-in. screen. Duty

depends upon the character of the ore, size of feed and product, weight of stamps, number of drops per minute, height of drop, drop sequence, shape of mortar, character of mortar foundations and condition of shoes and dies.

Capacities of stamps of various weights treating different kinds of ore are given in Table 34. Capacities of stamps of different weights on the same ore are given in Table 35.

Table 35. Effect of weight of stamp on capacity. (*After Caldecott, 19 IMM 57*)

Drop = 8 in. in all cases.

Size of feed. The effect of size of feed on stamp duty is a moot question. Beaver (*81 J 748* [*1906*]) gives the results shown in Table 36 for tests on a 1050-lb. stamp, showing maximum duty with feed between 1- and 1.5-in. But while this is the general trend of experience, the location of the maximum

point is not definitely fixed. It will, of course, vary with the weight of the stamp. Caldecott (*19 IMM 57*) thinks 1.75-in. the maximum economical size for unaltered Rand banket and says that fine feed distributes the blow and is, therefore, uneconomical. Way, commenting on Caldecott's data, suggests the possibility of increasing efficiency by feeding fine roll-crushed material and using light stamps and a large number of short drops. This practice would, however, entail such a complicated plant, consisting of breakers, rolls, stamps and tube mills, that any increased crushing efficiency would be far outweighed by the disadvantages of complexity. Several plants using coarse battery screens and finishing in tube mills report an increase in tons finished per horsepower-hour following the installation of a by-pass screen ahead of the battery with covering of the same aperture as the battery screen. Clark (*109 J 834*) says that a 900-lb. stamp can handle 3-in. feed and that no gain follows from decreasing the feed size below 2-in.

Table 36. Effect of size of feed on capacity of stamps. (*After Beaver*)

Size of feed; all pass. . . .-in. aperture	Duty, tons per 24 hr.
2.5	4.04
2	4.10
1.5	4.60
1	4.74
0.5	4.35
0.25	4.10

Size of product. Fine crushing in the battery reduces capacity by reason of the fact that material must be kept in the mortar a longer time and subjected to a greater number of blows of the stamp before discharge, therefore all of the factors that tend to produce a finer product tend to reduce capacity. The size of product is determined by the aperture of the screen, the quantity of water, the height of discharge, and the character of the screening surface.

Table 37. Effect of battery screen on stamp duty. (*After Caldecott, 19 IMM 57*)

Battery screen, aperture, inch	Duty per nominal stamp(*a*)	Tons of −90-mesh product per 24 hr. per nominal stamp
0.404	15.68	3.85
0.272	13.33	3.69
0.197	12.34	3.84
0.135	12.74	3.83
0.121	11.00	3.83
0.053	7.24	3.15
0.028	6.49	3.36

a A nominal stamp or NOMINAL CRUSHING UNIT (*N.C.U.*) is defined by Caldecott as a stamp with a running weight of 1250 lb. and an assumed new weight of 1350 lb. running at 100 drops of 8-in. set height (7½ in. actual) per minute. Stamps of other weight represent *N.C.U.* proportional to their weight, *e.g.*, a 1400-lb. stamp = 1.12 *N.C.U.*

Screens. Increase in screen aperture increases stamp duty, but the increase is substantially all in the coarse sizes. (See Table 37.) Table 38

Table 38. Effect of screen aperture on stamp performance. (*After Schmitt*)

Screen aperture, inch	Tons per 1400-lb. stamp per 24 hr.	Sizing test of product			Tons −90-mesh per stamp per 24 hr.
		+60-mesh	+90-mesh	−90-mesh	
0.27	15	62	10	28	4.2
0.20	14	59	11	30	4.2
0.15	13	56	12	32	4.15
0.09	10	47	14	39	3.90
0.07	9	43	14	43	3.87
0.028	7	31	16	53	3.72
0.02	6	22	18	60	3.58

shows that increase in aperture from 0.02- to 0.27-in. increased duty from 6 to 15 tons but the corresponding change in tons of −90-mesh product per day was only from 3.58 to 4.2.

At Homestake a similar change from 0.022- to 0.25-in. screen increased duty from 4.5 to 8 tons but decreased −200-mesh product from 2.4 to 1.9 tons per stamp per 24 hr. At the Giant mine, Rhodesia (*87 J 543* [*1909*]), the amount of −120-mesh product increased from 20 to 31 per cent. with decrease in size of battery screen from ½- to ⅜-in. Hardinge (*89 J 221* [*1910*]) states that the duty of 1000-lb. stamps crushing hard quartz was increased from 2.5 to 10 tons on increasing the aperture of the battery screen from 20-mesh to 0.25-in. The sizing test of the product with the larger screen was 13 per cent. on 10-mesh, 11 per cent. on 20-, 17 per cent. on 40-, 10 per cent. on 60-, 17 per cent. on 100- and 32 per cent. through 100-mesh. At Nipissing (*48 A 14*) change from 20 stamps with 0.077-in. and 20 with 0.178-in. screens to 20 with 0.261-in. and 20 with 0.408-in. screens increased the duty from 5.7 to 6.7 tons.

Screening surfaces that have a large percentage of opening produce a coarser discharge than those having a small percentage of opening because with restricted egress, material must be crushed smaller to pass through readily. Apertures convergent outward tend to clog and thus not only reduce the size of the aperture but also the percentage of opening and both of these factors produce finer product. The area of the screen surface does not seem to be of great importance, judged from the fact that multiple-discharge mortars do not increase capacity sufficiently to pay for the increased cost of screen wear. Most of the screening is done in a narrow strip at the lower edge of the screen and any given part of this area is worked only about one-fifth of the total time. The layer of feed has time to drain away between successive presentations of pulp to be screened so that each new presentation is made to a bare screening surface and the area provided in the usual single-discharge 5-stamp battery is sufficient. Munroe (*9 A 84* [*1880*]) points out that if this were not so, *i. e.*, if crushing capacity were in excess of screen capacity, increase in falling weight, which is not accompanied by any sensible increase in falling velocity, would not increase capacity, because it would in no way affect screening capacity. This is not rigorously true, because increase in the amount crushed per blow increases the proportion of fines in the pulp splashed against the screens, which, of course, makes the task of the screens easier.

Height of discharge is the vertical distance from the top of the die to the top of the lower rail of the screen frame. The height of discharge increases as the dies wear. In order to keep it constant, as should be done, chuck blocks of different heights are provided which vary the height of the screen above the bottom of the screen opening. For closer regulation slats 1 to 1½ in. thick are used between the bottom of the screen and the top of the chuck block. The height of discharge may also be varied by use of a false bottom under the dies but this practice is not favored because of the effect on the character of impact.

High discharge results in low capacity by reason of the tendency of the coarser material to settle and not be lifted to the screen surface. Small discharge height should be used for large capacity and high discharge when a fine product is desired at the expense of high capacity. The tests shown in Table 39 consistently bear out the conclusion that, with a given screen, increase in height of discharge results in decreased tonnage and increased fineness of product. The effect is least with the finest screen. With high discharge, the size of screen aperture, within the limits of these tests, has no appreciable effect on either tonnage or size of product, but with low

discharge the tonnage is materially decreased and fineness materially increased by change to a finer screen.

Table 39. Effect of height of discharge on stamp crushing. (*After Meinke, 100 J 763*)

6	0.024	5	2.97	2.3	6.7	6.9	6.3	26.9	50.9

Water. If the quantity of water fed to the battery is small the discharge is fine because the velocity of water-flow through the battery is not sufficient to carry the heavier particles in suspension and there is a lack of water to wash particles through the screen. The high viscosity of thick pulp reduces the rate of flow through the screen apertures, but, conversely, increases the carrying power for coarse material. If water is fed on top of the stamps, as is the most usual practice, part of the stream flows down over the screen and washes fine material away from the apertures. This effect is more marked the finer the screen. Individual jets introduced through the back of the mortar at the level of each die are probably the most effective in the case of coarse screens, but with fine screens such jets, unless operated at low velocity, wash coarse material against the screens and cause blinding.

Pitt (*8 JCM 373*) recommends for fine and medium crushing that the water be so introduced as to flow down the back of the mortar and thence forward across the dies. West (*116 P 7*), stating the duty of 950-lb. stamps on the Mother Lode, Cal., as 7.5 tons through 20-mesh screen, when making 110 @ 7½-in. drops per min., notes a water-solid ratio of 2.4 to 1 and states that increase in water would have increased the capacity. He also states that coarse crushing requires more water than fine. Recent practice is to use coarse screens and a small amount of water. Carpenter (*116 P 288*) records a duty for 1400-lb. stamps of 20 tons per 24 hr. through 1-in. screen with 2.6 tons of solution per ton of ore and expresses the opinion that doubling the solution would not increase duty 10 per cent.

Weight of stamps varies from about 900 to 2000 lb., this weight being that of the falling part including shoe, boss head, stem and tappet. The distribution of weight between the various parts is given in Table 30. The trend in the United States is toward stamps weighing from 1250 to 1500 lb. South African practice goes toward yet heavier stamps up to 2000 lb. Increase in weight causes increase in capacity (see Tables 34 and 35) but has little effect on size of product, all other things being constant. Tests 1 to 3, Table 35, indicate considerably more effect on tonnage crushed of the 80-lb. difference between 1 and 2 than for the 250-lb. difference between 2 and 3. On the other hand, as between tests 4, 6 and 8 the rate of increase in capacity with increase in falling weight is substantially uniform. Within the range covered this is probably the proper conclusion. Increase in weight is accompanied by increased breakage of cam shafts and stems, greater screen wear and metal consumption.

Height of drop. The amount crushed per drop increases with increase in height of drop. Meinke reports that 900-lb. stamps making 100 @ 6-in. drops per min. with 8-in. discharge height crushed 2.66 tons per stamp and with

7-in. drops, 3.05 tons per stamp per 24 hr. This is substantially direct increase. Munroe has shown, however, that more ore is crushed per blow of a given foot-pound value with a short drop and heavy stamp than under the reverse conditions. Louis (*28 A 553 [1898]*) has shown that the actual falling velocity is less than theoretical by a sensible amount (see Fig. 58), and has taken a series of stamp-indicator cards which show that the actual ultimate velocities range from 85 per cent. of theoretical with 82 @ 6½-in. drops per minute to only 63 per cent. with 93 @ 8-in. drops. Since the force of the blow struck varies as the square of the ultimate velocity, these figures correspond to losses of 30 to 60 per cent. due to friction and pulp resistance, the loss being greater with the higher drop. Further, the short drop permits more drops per minute, hence the line of development has been toward heavy highspeed stamps. High drop causes greater splash in the battery and, therefore, more rapid discharge.

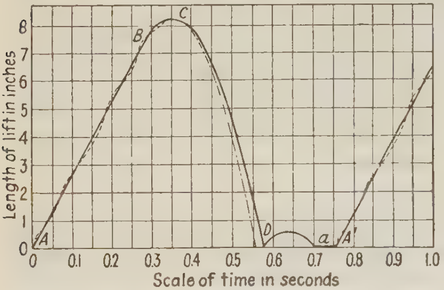

Fig. 58.—Stamp-mill diagram.

Eight-in. lift, 80 drops per min. Dotted line, actual rising path; dash-dot line, theoretical graph of fall.

Speed. The amount crushed per unit of time increases directly with the number of drops per minute. The amount discharged shows a similar increase in wet-crushing batteries, but in dry-crushing batteries the increase in amount discharged is out of all proportion to the increase in speed. Munroe reports an increase in yield of 122 per cent. for an increase from 60 to 90 drops per minute and an increase of 55 per cent. for a speed change from 90 to 102 drops.

The number of drops per minute and height per drop are interdependent, as may be seen by reference to Fig. 58, in which the portion of the curve from (A) to (B) represents the time when the cam is in contact with the tappet, that from (B) to (C) the time required for the upward momentum to be lost, that from (C) to (D) the falling time, that from (D) to (a) the time for rebound, and that from (a) to (A') rest time. Clearly, the time for a cycle with a given drop cannot be shortened beyond the point where the stamp is picked up on the rebound without danger of camming. If, however, the height of drop is lessened, the time for completion of a cycle is correspondingly decreased and the number of cycles or drops per minute can be increased. The force of the blow struck by the falling stamp can then be kept up by increasing the weight of the stamp. As above stated, the trend of modern practice in which stamps are heavier, has been to make drops shorter and speeds higher than formerly. The limit is reached when the force of the falling stamp is insufficient to break the largest particle of ore in the feed. The average of present-day practice is 100 @ 6- to 8-in. drops per min.

Condition of shoes and dies has a great effect on the capacity of the battery. These parts tend to wear unevenly; when wear has passed a certain point the capacity is greatly decreased.

Power for stamps varies with the weight of stamp, height of drop, and number of drops per minute. The theoretical power required may be cal-

culated by the formula $HP = WHN/(12 \times 33{,}000)$, where W is the weight per stamp in pounds, H is the height of drop in inches and N is the number of drops per stamp per minute. The total theoretical power for a battery is this figure multiplied by the number of stamps. The actual power consumption exceeds the theoretical by from 16 to 70 per cent. An allowance of 25 to 30 per cent. excess is safe for purposes of estimate. Tons crushed per horsepower-hour averages, according to Table 34, 0.074 with battery screens finer than 0.05-in. aperture, 0.138 for apertures from 0.05- to 0.25-in. and 0.164 for apertures coarser than 0.25-in. Truscott is quoted (*111 J 200*) to the effect that South African performance averages 0.05 ton per hp.-hr. from −2-in. through 30- to 40-mesh screen, 0.1 ton through 12- or 16-mesh, and 0.2 ton through 3- or 4-mesh. These figures are of the same general order as the preceding.

Moisture in product. Present-day practice is universally wet crushing. Table 34 shows a range in the percentage of moisture in pulp discharged through the screen from 75 to 94 per cent. The average of Rand practice is about 85 per cent. with a range of 50 to 90 per cent. The quantity of water used per ton is less with coarse screens than with fine and less the smaller the height of discharge.

When lime-bearing solution is being fed, all water lines should be of generous cross-section, nozzles should be at least 1-in. diameter, and all lines should be in duplicate with provision for easy replacement.

Feeding is universally done by means of automatic feeders in order to secure a supply of ore to the stamps properly regulated in proportion to the crushing done. Irregular feed not only decreases capacity, but increases breakage of stems and cam shafts. The Challenge feeder (Sec. 20, Art. 4) is most commonly used. The Tullock feeder is occasionally used. The Challenge feeder is the most satisfactory, especially on wet and sticky ores. It is operated by means of a small tappet on one, usually the center, stamp stem. The length of stroke of the feeder and consequently the quantity fed are determined by the distance that the stamp falls. Therefore, when material piles up in the battery the stroke is shortened and the quantity of feed automatically lessened and *vice versa*. The feeder is set up either suspended or supported, but in either case is arranged to slide out of the way when access to the space behind the stamps is desired.

Lost time in stamp mills is due to breakage of parts, principally stems, shoes, cams and cam shafts; dropping of boss heads or shoes; slipping of tappets, pulleys, or cam-shaft collars; renewal of shoes, dies and screens; regulation of height of discharge and height of drop; and dressing or cleaning plates inside and outside the battery. The latter cause is not directly chargeable to the stamp as a crushing device. Losses due to the other causes range from 1 to 11 per cent. (see Table 34).

Cost of crushing in gravity stamps ranges from \$0.15 to \$0.50 per ton.

At Homestake with 1000 @ 900-lb. stamps the cost in 1913 was \$0.36 per ton, making a product 81 per cent. − 100-mesh. Comparative costs at Simmer and Jack Proprietary with heavy stamps and tube mills was substantially the same but the ore was much harder (*22 IMM 185*). The cost of stamping alone at Simmer and Jack East in 1907 with 0.016-in. screen aperture, making a product containing 11 per cent. +0.01-in. material at the rate of 5 tons per 1350-lb. stamp per 24 hr. was \$0.45 per ton. Placing 0.057- and 0.035-in. screens on the stamps, thus raising the duty to 8.33 tons and re-grinding in tube mills reduced the percentage of +0.01-in. material to 1.6 without changing the cost of grinding (*19 IMM 57*). Cost at Alaska-Treadwell in 1915 ranged from \$0.17 to \$0.21 per ton in the 5 mills. At Churchill Wonder (1913–1914) (*52 A 128*) cost was \$0.081 for labor; \$0.073 for power; \$0.031 for supplies; total, \$0.185 per ton. At nipissing (*31 Ont. Dep. Mines 259*) forty

1500-lb. stamps crushing from 1½-in. to 4-mesh cost $0.10 for labor, $0.07 for supplies, $0.11 for power, $0.03 for shop; total, $0.31 per ton (aver. 1913–1922).

19. Nissen stamp

Description. The Nissen stamp unit consists of a single stamp falling in an individual mortar which is cylindrical in horizontal section. Two stamps mounted in a frame similar to that used with the 5-stamp battery constitute a unit and require about the same floor space as one 5-stamp battery. The screen extends more than half-way around the mortar and has an area of 3.75 sq. ft. which is about 3½ times as much per stamp as in an ordinary single-discharge 5-stamp battery. The mortar is made of semi-steel with manganese-steel liners. The total weight of a steel-frame battery ranges from about ten times the falling weight for a one-stamp unit to five times for a four-stamp unit.

Performance. Nissen (*12 JCM 357*) claims the performances given in Table 40.

Table 40. Performance of Nissen stamps. (*After Nissen*)

An exhaustive competitive run of Nissen *vs.* ordinary gravity stamps was made at the City Deep mill on the Rand in 1911. The results are given in Table 41. A less exhaustive test at the Northern Customs Concentrator Co., Cobalt, Ont. (*31 CMJ 87*), showed a duty of 5.5 tons per 24 hr. through 30-mesh screens for a 1650-lb. Nissen stamp against 2.25 tons per 1250-lb. stamp in a 5-stamp battery; the power consumed by two of the Nissen stamps was 40 to 50 per cent. less than that for the five 1250-lb. stamps; the feed was a hard conglomerate crushed through 1.5-in. The +40-mesh in the Nissen-stamp product was 8.6 per cent. and the −200-mesh, 43.4 per cent. against 5.2 per cent. and 48.8 per cent., respectively for the 5-stamp battery. A similar comparative test at Tincroft, Cornwall (*11 MM 378*) showed 11.4 tons per stamp day for a 2000-lb. Nissen *vs.* 7.2 tons for a 1250-lb. standard stamp; the respective tons per hp.-hr. were 0.09 and 0.08; the products were substantially the same, *viz.*: 13 to 16 per cent. +20-mesh and 26 to 27 per cent. −200-mesh. The 5-stamp mortar was particularly narrow with straight back and steep front. At Modderfontein B (*114 J 836*) California stamps crushed through 6-mesh Ton-cap with a consumption of 6.5 hp.-hr. per ton; Nissen, through 9-mesh Ton-cap, 4.4 hp.-hr. per ton.

Advantages claimed by Nissen over the ordinary 5-stamp battery are as follows: (1) It is difficult to distribute feed evenly to the dies in the 5-stamp mortar while in the Nissen the feed is led directly onto the single die and each rise of the stamp causes the pulp in the mortar to flow toward the center of the die. (2) The area of screen per stamp is greater in the Nissen and the pulp is presented to the screen along a normal to the surface instead of at an angle, as is the case with most of the pulp in the 5-stamp mortar. Both

differences make for more rapid screening and hence greater capacity in the Nissen. (3) Cam-shaft breakage is less in the Nissen because of the smaller loading (two stamps to be lifted between bearings *vs.* five in the ordinary battery). The diameter of cam-shafts in the ordinary battery cannot be further increased owing to the resulting increased velocity of pick-up. (4) The limit of weight (and, therefore, capacity) of a 5-stamp battery has been reached on account of the incre se in size of mortar and in length of cam-shaft necessarily attendant upon further increase in diameter of falling parts or, if the increase is gained by increase in length of head and weight of tappets, stem breakage is increased, due to the great length below the lower guide and to vibration caused by the heavy tappets. A larger mortar means greatly increased difficulty in anchoring the mortar and also greater strains in the mortar itself. In the Nissen stamp the weight is concentrated near the shoe by use of a shouldered boss, consequently vibration is lessened. (5) Shoes and dies wear more evenly in the Nissen stamp, due to even return of the uncrushed material to the die and great rotation of the stamp, hence the faces are flatter and the capacity correspondingly greater. (6) Power and steel consumption are less on account of the higher discharge rate gained by favorable screen placing.

20. Pneumatic stamps

Description. Pneumatic stamps, also called CRANK STAMPS and HIGH-SPEED STAMPS, have had limited use. The Holman (Fig. 59) is the best known. It consists essentially of a cylinder (*a*) attached by means of trunnions (*b*) and connecting rods to the driving mechanism. A crushing member consisting of shoe (*c*) and boss-head (*d*) is mounted on the lower end of a piston rod (*e*) that runs through the cylinder and carries piston (*f*). Air ports are provided in the cylinder walls, one set for use with new shoes and dies, the other when shoes and dies are half-worn. The piston itself acts as a valve, closing the lower ports on the up-stroke and the upper ports on the downstroke and thus providing air cushions that protect the cylinder heads. The stamp is run at 120 to 140 @ 12-in. strokes per min. and requires from 30 to 35 hp. per unit of two stamps.

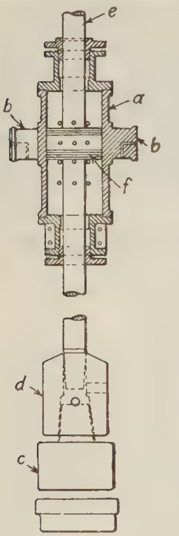

Fig. 59.—Pneumatic stamp.

Performance. At EAST POOL, Cornwall (*86 J 213*) one 2-stamp unit crushed 21 tons per 24-hr. of −3-in. feed through a 25-mesh screen. The capacity of a 950-lb. gravity stamp on the same feed is 1.4 to 1.5 tons per 24 hr. At MOUNTAIN QUEEN, West Australia (*95 J 108*) a 2-stamp unit crushed 135 to 160 tons per day of fairly hard ore through a 10-mesh screen. Metal consumption was 0.45 lb. per ton; water, 1200 gal. per ton. At BABILONIA GOLD MINES, Nicaragua (*113 P 911*), a 2-stamp unit making 145 to 150 drops per min. crushed −2.5-in. feed through 6- and 9-mesh wire screens at the rate of 25 tons per stamp per 24 hr. Water consumption was 9 tons per ton of ore. Mortar liners lasted 4 months, stems 3 months, screens 3 days. Wear of shoes was 0.48 lb. per ton and of dies, 0.17 lb. per ton. The product contained 50 per cent. +20-mesh and 12 per cent. −200-mesh.

21. Stamps *vs.* other crushers

Stamps *vs.* stamps plus tube mills. Table 42 shows the reasons that caused the change from stamps to stamps plus tube mills for fine grinding

Table 42. Stamps *vs.* stamps plus tube mills at Simmer and Jack East

Per cent. +0.01-in. material in product	10.9	1.6
Cost, dollars per ton	0.3515	0.3578

for cyanide work. By putting coarser screens on the stamps (0.057- and 0.035-in. instead of 0.016- and 0.017-in.) and sending the sands to tube mills for regrinding, the stamp duty was increased from 5 tons per 24 hr. to 8.33 tons and the percentage of material remaining on a 0.01-in. screen was reduced from 10.9 per cent. with stamps alone to 1.6 per cent. with stamps plus tube mills, with an increase in cost per ton ground of 0.63¢. Later

practice uses still coarser screens on the stamps and more tube mills, with resulting increased production of fine material per unit of cost. As early as 1909 the Mines Trials Committee on the Rand reported (*So. Af. Min. Jour., Oct. 9, 1909*) that crushing to 3-mesh in stamps with final reduction in tube mills would give a stamp duty of 15 tons per 24 hr. with a 1400-lb. stamp and represented the maximum economy with these machines.

Stamps vs. rolls. Reid (*17 CMI 56*), analyzing the factors determining the choice between stamps and rolls as intermediate crushers for Cobalt mills, says that stamps were used because of the anticipated short life and low capacity of the mills, while the ore was tough and required fine crushing to free the mineral. Rolls alone could not finish to the required fineness and several in series would have been needed, together with a final fine grinder, to accomplish the size reduction possible with one set of stamps. This would have meant a complicated flow-sheet and more slime would have been produced than with the stamps. Furthermore, on account of the small capacity of stamp units, heavy stamps can be used with resultant economy, while rolls of the size and weight necessary for economical operation would have great excess capacity.

Stamps vs. ball mills. The general and probably the correct conclusion on this question, when all-slime cyanidation is the metallurgical aim, is that stamps are superior for small tonnages of hard ore, but that for any tonnage that will justify the use of a 6-ft. ball mill or larger, ball mills followed by tube mills will be the most economical combination. The stamp has the advantage for small tonnages that it can finish to slime from as coarse as 3-in. feed at one operation, which a small ball mill cannot do and a large one cannot do economically; the stamp unit is of small capacity and hence the most efficient size can be chosen, even for small mills; and the small capacity per unit permits one unit to be cut out for repairs without serious diminution of mill capacity. On the other hand, for large tonnages, when the choice is between stamps plus tube mills and ball mills plus tube mills, the ball mill does more crushing per unit of power input than the stamp, has a much smaller percentage of lost time, takes less attendance, has fewer parts and is, therefore, less complicated; the foundations are simpler, it takes less mill room, the first cost is less, and it is less noisy. Steel consumption probably averages less in the stamp, but if the stamp is charged with broken stems, cams, camshafts and discarded tappets, the difference in its favor quickly disappears.

At a Canadian mill (*113 P 260*) eighty 1250-lb. stamps crushed 800 tons per day through ⅜-in. screen with a consumption of 7.2 hp.-hr. per ton milled. One 6-ft. ball mill crushed 498 tons per day to substantially the same size, consumed 5.3 hp.-hr. per ton, and required about the same floor space as 10 stamps but less mill height and mill construction.

SECTION 4

FINE GRINDING. CRUSHING EFFICIENCY

In present-day terminology, fine-grinding machines are those that deliver the finished product well under a millimeter in maximum size. The machines most commonly used for this work are cylinder mills, including ball mills, tube mills and rod mills; gravity stamps; and, in comparatively rare cases, Chilean mills, Huntington mills, and grinding pans. The great bulk of fine grinding in concentrating mills is done by the first three types. Stamps as fine grinders are now found only in occasional gold mills of small size. Huntington mills have practically disappeared. Chilean mills have a limited use in small, isolated precious-metal mills. Pans have never had wide use and have been supplanted by more modern machines in practically all places. Their only claim to consideration at the present day is small first cost.

CYLINDER MILLS

The term cylinder mills is herein used to describe machines that consist essentially of hollow containers of circular cross-section, mounted with the axis substantially horizontal, and partially filled with crushing bodies that are caused to tumble, under the influence of gravity, by revolution of the container. There are several different types. The usually accepted primary classification is based on the character of the crushing bodies and groups the machines as: (1) ball mills, in which the crushing bodies are usually metal spheres, although other shapes such as cones, cubes, octahedra, short cylinders and the like have been tried; (2) pebble mills, using flint pebbles or selected lumps of local hard rock or ore as crushing media; (3) rod mills, in which straight metal rods of cylindrical or polyhedral section and substantially as long as the cylinder form the tumbling mass. Ball mills are further classified as (*a*) cylindrical mills with trunnion feed and simple trunnion discharge, called CENTER-DISCHARGE OR OVERFLOW MILLS; (*b*) cylindrical mills with

trunnion feed and an accelerated trunnion discharge accomplished by some type of pulp elevator at the discharge end, called PERIPHERAL-DISCHARGE or GRATE MILLS; (3) conical mills; (4) cylindrical mills with trunnion feed and discharge through a peripheral screen, often called KRUPP MILLS. Pebble mills with cylindrical shells are called TUBE MILLS and those with cylindro-conical shells, CONICAL PEBBLE MILLS. A rod mill commonly has a cylindrical shell but the cylindro-conical shell has been tried successfully.

1. Center-discharge mills (Overflow mills)

These consist essentially of a cylindrical shell of heavy metal partially closed at both ends by metal heads carrying hollow trunnions. The cylinder is mounted horizontally, usually on trunnion bearings but occasionally on a tire and rollers at one or both ends. A gear mounted on the outside of the cylinder is driven by a pinion shaft, suitably mounted at one side and actuated by various means. Balls up to 7-in. diameter are charged until the mill is filled to within a few inches of the axis. Feed is introduced through one of the trunnions and the ground product flows out at the other end. Mills range from 3 to 8 ft. in diameter and from 2 to 8 ft. in length. Ordinary sizes are given in Table 1.

Table 1. Cylindrical ball mills. Size, weight and operating data, from makers' catalogs

A 9 × 6-ft. mill is being tested at Inspiration; see page 359.

Shell of most ball mills is cast iron, cast semi-steel or cast steel, made extra thick, and flanged at the ends for attachment to the heads. The joint between head and shell is

made with tongue and groove in order to distribute shearing stresses and take some of the load off the bolts. Long shells are usually segmented with flanged joints similar to those at the ends. The Marcy mill is cast in two parts with heads integral and has a flanged joint at the center of the barrel. The shell is drilled for liner bolts. Some manufacturers cast the shell with one and some with two manholes. In short mills the manholes are frequently placed in the heads. Manholes are made large enough to allow for the introduction of liner plates. Power is saved by providing manholes on opposite sides of the mill.

Heads are cast, of iron, semi-steel or steel, and heavily ribbed. Some manufacturers cast the trunnions integral with the heads, others cast heads and trunnions separately, the latter with a heavy flange, and after facing both head and trunnion accurately, bolt the two together. The assembled mill should be swung in a lathe and the trunnions turned true with the mill axis, then polished. Some manufacturers provide trunnions with steel sleeves pressed on before turning down, to protect the main casting from wear. This is probably an unnecessary refinement.

Trunnion bearings are made very large and heavy. Some makers provide rigid bearings, other ball-and-socket type. It is probable that the latter give better service. The lower half of the bearings is babbitted, the upper half is cored out to form a large pocket for lubricant. Some manufacturers furnish a tire-and-roller bearing instead of a trunnion at the discharge end. This type of bearing takes less power than the trunnion bearing when new, but it is difficult to maintain even wear on tires and rollers and, as a consequence, after a short time such a mill is likely to get out of alignment, then vibration and power consumption increase markedly. Renewal of tires and rollers is expensive and slow as compared with the renewal of babbitt in ordinary trunnion boxes, particularly as compared with the renewal of removable babbitt linings, where such are used.

Lining. Shells are usually lined with replaceable metal plates bolted to the interior surface. The best design is one that allows easy replacement of individual sections. Liner materials are commonly hard iron or manganese or chrome steel. Hard iron is unsatisfactory because of breakage, when balls larger than 2-in. diameter are used. Cast manganese steel is widely used and has been particularly successful with heavy charges of large balls. Cheaper materials, having less strength and toughness than manganese steel are satisfactory with light loads and will probably be considerably cheaper. Manganese steel for linings must be very tough. It may be of satisfactory chemical composition, yet, through improper heat treatment, wear even more quickly than cast iron (*122 P 465*).

Plates are made in a considerable variety of sections. Typical sections are those that give a smooth interior surface and those that give a ribbed surface with ribs parallel to the axis of the mill (see Fig. 1). The liners (*A*) and (*B*) (Fig. 1) consist of individual plates bolted directly to the shell, while in (*C*) and (*D*), the plates are held in by wedge-shaped bars. The advantage of the latter construction is greater ease in drawing plates into place.

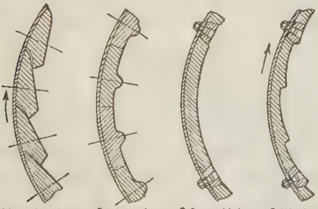

Fig. 1.—Liners for ball mills.

End liners of the same metal as the shell liners are used to protect the heads. Liners are also used for feed and discharge trunnions. These latter may be made with smooth inner surfaces or may have a helical groove cast inside, the feed-trunnion liner having the groove directed to facilitate entrance of feed, while the discharge-trunnion liner has the grooves directed to return coarse material into the mill and to aid in feeding balls into the mill against the flow of discharging pulp. A grooved liner for the feed trunnion has the disadvantage that it limits capacity when a feeder of

excess capacity is used in the attempt to force large quantities through the mill. THICKNESS OF LINERS ranges from 2 in. in small mills to as much as 5 in. in mills of large diameter.

A special lining for a 4 × 10-ft. ball-tube mill at LIBERTY BELL (see Table 4) was made by cementing in alternate courses of 1¾ × 2 × 5 × 48-in. hard-chilled cast-iron bars and 4½ × 5 × 8½-in. quartzite blocks, set with the 4½-in. dimension radial; no bolts were used. For one lining, 200 quartzite blocks, 42 ribs, 9 sacks of cement and 9 sacks of sand were required. Consumption was 0.65 lb. quartzite and 1.25 lb. iron per ton of new feed.

Fig. 2 (*122 P 465*, *112 J 778*) shows a lining made of steel rail, designed to pick up a ball layer in the same way that the El Oro lining picks up pebbles (see p. 427). Lining for a 6 × 5-ft. grate mill using 4-in. balls and crushing −1-in. material is composed of 50-lb. re-laying rails with ⅞-in. bolts. A complete liner cost about $250 (1921), which was one-tenth the cost of a manganese-steel liner. It lasted 5 months on open-circuit work grinding to −⅛-in. The cost of balls lodged in the liner must also be charged. A similar lining in a 5 × 6-ft. center-discharge re-grinding mill (−⅛-in. to 95 per cent. −100-mesh) lasts about 15 months using 2-in. balls. A white-iron plate lining in the same mill lasts about 5 months and costs twice as much.

FIG. 2.—Rail liner for ball mill.

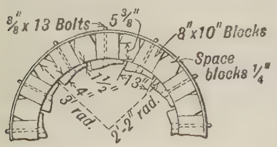

FIG. 3.—Method of reducing diameter of a cylinder mill (*after Daman*).

A ball mill at CATEMU, Chile (*123 P 884*), was lined with steel rails set in cement. The lining gave no trouble and wore well.

Liners are sometimes blocked out from the shell by wooden filling in order to reduce the internal diameter of the mill. Fig. 3 (*103 J 111*) shows the method employed at NEVADA PACKARD in changing a 6 × 5-ft. pebble mill into a ball mill. Twelve hours were required to empty the pebble mill, change liners and re-fill with balls.

Balls are made of forged high-carbon or chrome steel or of cast iron or manganese steel. Wraight (*30 IMM 208*) gives the analyses in Table 2 for three different samples. Lawler (*112 J 5*) states that most balls are made of assorted scrap of unknown composition with carbon content varying from 0.2 to 1 per cent when the proper limits are 0.6 to 1 per cent., that the chrome in chrome-steel balls varies from *nil* to 0.05 per cent. and that balls from most small forges will vary greatly from shipment to shipment. The usual sizes are from 2- to 6-in. diameter. Fairchild (*116 J 197*) shows that if the balls are all of one size, the weight per cubic foot with close packing is 363 lb., corresponding to 26 per cent. voids. Davis (*61 A 276*) thinks 35 per cent. voids more nearly correct for calculating ball-mill loads. Tillson (*116 J 357*) says that the void in the charge of a cement mill has been found to be 44 per cent.

Table 2. Analyses of grinding balls.

Ball load. The most efficient ball load is probably all that a mill will hold which is normally about 55 per cent. of internal volume. The weight of a full charge may be roughly estimated from equation $W = 80\ D^2L$, in which W = weight in lb., D = nominal diameter and L = length, both in feet. In many mills, however, the ball load is carried as much as 8 to 10 in. below

the axis of the mill. It is usual to have a charge of mixed sizes, the maximum size depending upon the maximum size of feed. Table 3 shows common practice as to maximum size and proportion of various sizes of balls with different sizes of feed. The use of as small balls as will crush the largest rock is often recommended, but Young (*58 A 126*) found the best efficiency for 5-in. balls at all feed sizes. Balls added to compensate for wear are generally of the largest size only. The weight added is usually a fixed amount daily, determined by average consumption and tonnage treated. A better method of regulation is to determine the ammeter reading corresponding to maximum grinding efficiency and then to load balls as needed to maintain this reading. When maintaining the ball load near the mill axis, a drop in the ammeter reading following the addition of balls usually corresponds to an overload. For ball wear see p. 384. For other shapes than spheres see p. 400.

Table 3. Proportions of balls of various sizes in new ball loads. (*From Marcy catalog*)

Diameter of balls, inches	Percentage of total load	
	Coarse feed, 1-in. to 3-in. maximum	Fine feed, ⅛-in. to ½-in. maximum
2½	....	10
3	10	20
3½	20	40
4	30	30
5	40	....

Feeders are of three general types, known respectively as one-way scoop, three-way scoop, and drum. Occasionally a two-way scoop is used. ONE-WAY SCOOP (Fig. 4) consists of a single spiral with open end and central side opening for delivery into the feed trunnion. Extreme radii of spirals are 15, 24, 27, 30, 36, 42, and 48 in., depending on size of mill, size and tonnage of feed, and amount of elevation desired. The cross-section of the spiral passage is rectangular, and should be sufficiently large to pass freely the largest ball that is used in the mill. A steel-plate scoop was used at MIAMI COPPER CO. A THREE-WAY SCOOP contains three spirals of but one-third turn each and is designed to give greater capacity than a single scoop (but see Hines below). It is not made of as great radius as the larger single scoops. Both types revolve with the mill in a rectangular feed box from which they pick up a certain portion of material at each revolution. Spiral feeders serve the useful purpose of elevating feed as well as introducing it into the mill and therefore make possible a lower feed-delivery point. This is of distinct advantage when mills are run in closed circuit with mechanical classifiers. If feed is brought into the feed box on the up-coming side in the plane of revolution, the capacity of the feeder is considerably greater than when feed enters at right angles to this plane.

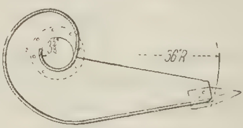

FIG. 4.—One-way scoop feeder.

DRUM FEEDER consists of a cylindro-conical receptable, open at both ends, with inside helix to transfer material from the feed side into the mill trunnion. It is superior to the scoop types for coarse feeds because it is more positive and less subject to breakage, but it requires to be fed at a higher elevation. The combination drum-and-scoop feeder (Fig. 5) is used when the original feed to the mill is coarse and can be delivered at the height of the mill axis and when sand oversize is delivered from a mechanical classifier. With this feeder, the usual box is made for receipt of classifier sand and from this sand is picked up by the scoop while coarse original feed is discharged directly into the drum.

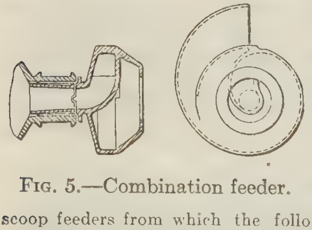

FIG. 5.—Combination feeder.

Hines (*59 A 249*) reports a series of tests on scoop feeders from which the following conclusions were drawn: (1) The capacity of a spiral feeder is proportional to the length of the spiral. (2) The capacity of a single-scoop feeder is twice to four times as great as that of a double-scoop, according to the form of the latter. (3) The capacity of a 3-way scoop is about half that of the single

scoop. (4) With coarse feeds the capacity of the scoop is limited by the trunnion and trunnion capacity is less with a spiral liner than with a smooth liner flaring into the mill. For largest tonnages of coarse material the trunnion must be short and of large diameter.

At ASTURIANA DE MINAS (*115 J 399*) the capacity of a ball mill taking −1.5-in. feed was limited by the feeder to 175 tons per 24 hr. The smallest section of the spiral was 5½ × 6-in. and the opening into the mill trunnion was 7-in. diameter. Capacity was increased to 200 tons by making the thimble between the scoop and the trunnion cylindrical instead of conical and then increasing the diameter of the central discharge opening from the feeder to 9 in. and placing a helix of 10-in. pitch through the feed trunnion.

Feeders are made either of cast iron or cast steel or built up of steel plate. It is well to provide for bolting either side to the trunnion, thus making the feeder reversible, a cover plate being provided for the outside. This is, of course, impossible with the drum and combination feeders. Replaceable lips of hard cast iron or manganese steel are usually provided for scoop feeders and in some cases liners for the spiral are also used. The great advantage in the use of the combination feeder lies in the fact that coarse material is kept out of the feed box. This prevents jamming of large particles between the moving scoop and the sides and bottom of the box with consequent racking of the box and strain on feeder and bolts.

Fig. 6 shows a special form of elbow feeder for ball mills. A screw feeder is sometimes used for soft, dry feed; at the T. P. KELLEY AND CO. graphite plant (*114 J 325*) scoop feeders failed while this type was successful.

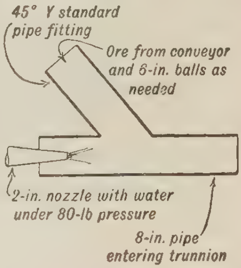

FIG. 6.—Sketch of ball-mill feeder at Hollinger.

Feed box is required for scoop feeders. It consists of a rectangular box built around the scoop, fitted closely around the thimble between the feed trunnion and scoop proper, with clearance all around the scoop greater than the largest lump of ore or the largest ball (or pebble) fed. Feed is introduced through suitable openings. The top should be protected with a grating.

Discharge trunnion is normally of slightly greater diameter than the feed trunnion in order to induce flow of feed through the mill. The end of the trunnion is fitted with a bell-shaped lip with, in some cases, drip rings to prevent sand from working back into the bearing. As previously noted, the trunnion liner may have a reverse helix cast on the inner surface.

Drive. The smallest mills may be driven directly by belt to a pulley mounted on the shell. This is cheap but most unsatisfactory, as the belt is likely to slip badly, especially at starting. All other mills have a gear mounted on the mill shell driven by a pinion on a countershaft at about the level of the mill axis. The cheapest drive, from the standpoint of first cost, is one with a machine-molded cast-iron spur gear on the mill, cast-steel cut pinion, and pulley-driven countershaft. A cast-steel cut gear is mechanically better but more expensive. Gears are reversible so that two wears can be taken on the teeth. A long-center horizontal belt is best from mechanical considerations, but takes up a lot of floor space. This difficulty may be obviated by using some form of short-belt drive with tightening pulley, such as the Lenix. With this drive the motor may be placed in any position with respect to the driven pulley, but on account of splash is best not placed below the mill axis. On account of the heavy starting load, clutches must be used with belt drives unless the belt and motor are greatly oversize. Any standard friction clutch is satisfactory, but it should be comfortab y oversize (50 to 100 per cent.) to withstand excessive starting strains and be well protected against grit. One form has the pulley mounted on a quill with a friction clutch. This makes for easier alignment than the ordinary friction-clutch pulley. Rarely a bevel gear is used in place of a spur gear on the mill but end thrust on the pinion shaft causes difficulty. Silent-chain drive of the mill countershaft has the same advantage as the short b lt and no slip at starting, but is more expensive. No clutch is required for the drive itse' , but one must be used in lieu of an oversize motor. Gear sets in various combinations are frequently used. The cheapest has the usual spur gear on the mill and a large gear on the mill countershaft, driven, through a flexible coupling, by a pinion on the motor. A more compact but somewhat more expensive arrangement uses a standard gear-speed reducer on the motor, attached through a flexible coupling to the mill countershaft. The gears in the speed reducer are enclosed, run in a bath of oil, and are more efficient and longer-lived than the open gear set first described. Both permit the use of high-speed motors. The most expensive but most efficient drive is a herringbone gear on the mill with a slow-speed motor direct-connected to the pinion shaft through a flexible coupling, ordinarily of the pin-and-bushing type. Speed reduction can be as great as 20 to 1, so that the motor speed required is from 300 to 600 r.p.m., according to

F = feed. *P* = product

the diameter of the mill. This drive showed 10 to 15 per cent. saving in power over ordinary belt-driven countershaft and spur gears on conical mills at CALUMET AND HECLA (*109 P 759*). Wormser (*114 J 763*) says that the opinion is commonly expressed at mills that he has visited that herringbone gears easily make up for the added cost in increased smoothness of operation. Dirt must be carefully excluded. A difficulty with direct connection is the end surge of the mill consequent upon the clearance that must be left between trunnion shoulders and mill bearings to compensate for expansion with temperature rise.

The pinion shaft is made of wrought iron or mild steel, of large diameter, set in long bearings with special provision made for aligning the countershaft with the mill axis. With herringbone gears some manufacturers attach the pinion-shaft bearings rigidly to the sole plate of the trunnio bearings, and attain alignment of mill and pinion shafts by moving the trunnion bearings on he sole plates.

Motors must be of a type that will stand heavy continuous duty at constant speed under constant load and must have large starting torque, ranging fr m 150 per cent. of full-load torque for long tube mills to 200 per cent. for short bal mills and rod mills. Wound-rotor motors are substantially necessary for large mills. Squirrel-cage motors designed for especially high starting torque may be sed for smaller mills. When clutches are used load conditions are ideal for synchronous motors. (See also Sec. 23, Art. 7.)

Individual drive is usual and, except in the case of a number of small mills, undoubtedly best from all points of view except economy in first cost. Group drive is more complicated and subject to mechanical difficulties, causes greater loss in plant capacity when out of repair, is more dangerous and more obstructive of headroom and floor space.

Performance of center-discharge ball mills is given in Tables 4 and 4*a*. Capacity ranges from 45 to 50 tons per 24 hr. in open circuit, reducing very hard ore from -1.5-in. to pass 10-mesh, to 900 tons per 24 hr. crushing soft ore from -9-mm. to -3-mm. Power consumption varies from 4.4 hp. per ton of balls in a 4×10-ft. mill to 18.9 hp. per ton in an 8×6-ft. mill; average for mills of typical shape (p. 345) is 13.2 hp. Tons crushed per horsepower-hour ranges from 0.162 to 0.276 in open-circuit crushing making 4- to 8-mesh product and is from 0.05 to 0.06 when making 10- to 20-mesh product.

2. Peripheral-discharge mills (Grate mills)

Cylindrical ball mill with peripheral discharge has a perforated diaphragm mounted near the discharge end and a pulp elevator located between the diaphragm and the discharge head. The original purpose of the grate was to hold back oversize material until ground to a size predetermined by the grate apertures, but this was quickly found to be impracticable and the function of the grate as now used is to confine the ball charge and to form a part of a quick-discharge device. In the type shown in Fig. 7 the discharge diaphragm (*a*) carrying gratings (*b*) is held against the discharge-end head by means of bolts (*f*). The diaphragm is protected by plates (*g*) and grating bars (*b*). The plates (*g*) are held by bolts (*e*) through the head and the grate bars are held in place by wedge blocks (*c*) which are in turn drawn up by bolts (*d*). The diaphragm carries a central discharge pipe (*h*), projecting through the center of the trunnion, which acts as an emergency overflow. If no such provision is made, an overloaded mill will discharge back through the feed trunnion and may require as much as two hours to work back to normal. Ribs (*k*) are cast

on the back of the diaphragm and serve as lifters to elevate pulp discharged through the diaphragm to such a height that it can flow out through the trunnion. The level of pulp at the discharge end of the mill is determined by the distance of openings (*l*) from the periphery of the mill. If all openings are free, the pulp level at the discharge end of the mill will be relatively low and the rate of flow of pulp through the mill will be a maximum for a given feed rate and moisture content. If it is desired to slow down the rate of flow, with consequent finer grinding at one passage, plugs are introduced into the outer ring of openings (*l*), working through hand-holes (*m*), or the pulp density in the mill is increased. In another type of grate mill variation in rate of discharge is got by adjusting the width of

radial lifting bars attached to the discharge-end head (Chalmers and Williams, adjustable quick-discharge ball mill). In yet other mills the rate of discharge is varied by varying the space between grate bars (Marcy).

The discharge grating is made of cast iron or cast steel, liner plates are normally made of manganese steel and grate bars of high-carbon or chrome steel. Grate bars may be rectangular in cross-section, or slightly wedge-shaped. Wedge-shaped bars are set with the greatest width toward the head end of the mill. There is less danger of clogging with wedge-shaped bars; on the other hand, the width of opening between bars increases as bars wear. Tangential setting of bars is favored by some manufacturers as giving freer discharge than radial setting. With this setting the pulp level may be varied

by replacing wedge-shaped bars near the periphery by rectangular bars, thus slowing down pulp egress. Ordinary spacing of bars is from 3/32 in. to 1/4 in., or, in rare cases, more; depth is made 3 to 3½ in.

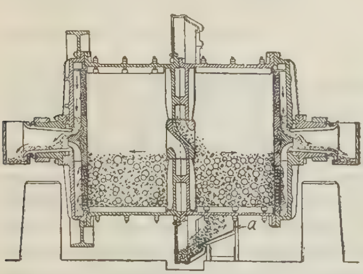

Fig. 8.—Fairchild double ball-mill.

Fairchild mill (Fig. 8) is a recent form of grate ball mill which aims, by central feed and double discharge to increase the tons ground per horsepower-hour by eliminating over-grinding. The feeder is of the double-spiral drum type and the grate and discharge show no variation in principle from standard forms.

Performances of grate mills at a number of plants are given in Tables 5 and 5*a*.

At Afterthought Copper Co. (*119 P 154*) a 6 × 4½-ft. Marcy mill grinds 150 tons per 24 hr. from 6 per cent. on 10-mesh with 20 per cent. − 200-mesh to 5 per cent. on 60-mesh with 67 per cent. − 200-mesh. Moisture, 25.4 per cent. Sand return is 803 tons. At Trojan plant (*114 J 763*) a 6 × 6-ft. mill with 5-in. balls grinds 400 tons per 24 hr. from − 2-in. to 3 or 4 per cent. on 10-mesh.

Capacity, according to the figures from practice given in Table 5, ranges from 50 tons per 24 hr. in a 4 × 4-ft. mill grinding in open circuit from −2- or −3-in. to 8- or 10-mesh to 800 to 850 tons in an 8 × 6-ft. mill grinding in open circuit from 1-in. to 10-mesh. At Inspiration a 9 × 6-ft. mill grinds 535 tons per 24 hr. from 2½- or 3-in. to 48-mesh. Power consumption is from 7.2 hp. per ton of ball load in a 7 × 10-ft. mill to 20 hp. in a 6 × 4½-ft. mill and averages 12.9 hp. per ton. Tons per horsepower-hour ranges from 0.063 to 0.300, crushing to table or tube-mill feed, the average of 14 mills is 0.147; crushing to flotation size the range is from 0.047 to 0.111 and the average of 6 mills, 0.080.

Manufacturers of cylindrical ball mills. Abbé Engineering Co., Allis-Chalmers Mfg. Co., Chalmers and Williams, Denver Eng. Works Co., Mine and Smelter Supply Co., Power and Mining Machinery Co., Traylor Engineering Manufacturing Co.

3. Grate mills *vs.* center-discharge mills

Grate mills consume more power, with a given ball load than simple trunnion-discharge mills, and steel consumption and repair costs per mill are also higher, but on most ores the capacity is sufficiently greater to more than counterbalance the higher operating cost. As a result the majority of cylindrical ball mills at the present time are grate mills. Tellam (*106 J 583*) states, on the other hand, that at Smuggler Union Mining Co. the capacity of a grate mill from 4- to 60-mesh was 3.03 tons per 24 hr. per hp. consumed against 4.67 tons in a center-discharge mill. Consumption of cast-iron balls in the grate mill was 2.5 lb. per ton and in the center-discharge mill 2 lb. As a result the grate was removed and the mill operated as a center-discharge mill. A similar conclusion was reached from a different point of attack at St. Joseph Lead Co. (*66 A 108*). Here the end sought was maximum production of −10-mesh material with minimum production of −150-mesh slime. Experiments showed that the desired condition corresponded to the maximum tonnage that could be forced through the mill, the circuit being closed on a 2-mm. screen. With a 6 × 4-ft. grate mill the feed rate was limited to 440 tons of −9+2-mm. feed, producing 340 tons −10-mesh material per day, by the fact that with more than 25 per cent. of +10-mesh material in the discharge the mill choked. The same mill without grate took 600 tons per day total solid and produced 390 tons of −10-mesh material. Del Mar (*106 J 14*) presents the data in Table 6 to show the effect of grate and lifters

Table 6. Comparison of products of a 4 × 4-ft. ball mill with and without quick discharge. (*After Del Mar*)

on the character of the mill product. He states that the maximum capacity of the mill with quick-discharge mechanism was 56 tons per day, while it ran up to 88 tons as a center-discharge mill. He attributes the difference to the large circulating load in the grate mill (see Test A) and to under-work near the discharge end due to low pulp level. His conclusions are not wholly convincing, due to lack of data concerning other operating conditions.

Differential grinding. It is frequently claimed that in closed-circuit grinding the sulphide mineral, being more friable than the gangue, is slimed more than the gangue and, further, that the center-discharge mill is a worse offender in this regard than the grate mill. Neither of these contentions is borne out by the available data. In Table 7 it is seen that in the tube-mill feed, considering the -200-mesh material, 14.7 per cent. of the total solid contains 25.7 per cent. of the total sulphide, while in the classifier overflow 81.3 per cent. of the total solid carries only 85.1 per cent. of the total sulphide, a distinct impoverishment of the slime, relative to the coarser grades, in the process of grinding and classifying. Comparing the results in Tables 8 and 9, and considering -200-mesh material, the first shows 0.87 per cent. of the total lead in 0.2 per cent. of the total solid in the mill feed, while in the product 23.8 per cent. of the total solid contains only 44.97 per cent. of the total lead. Considering the oversize and undersize on 100-mesh, the former assays 6.03 per cent. Pb and the latter 11.8 per cent. in the feed; the former 4.52 per cent. and the latter 13.6 per cent. in the product. Here there is undoubtedly some concentration, indicating differential grinding. Taking the ratios of the assays as a measure of the concentration, the ratio of assays of fine to coarse in the feed is 1.96, and in the product, 3.01. The ratio of these ratios is, then, an index of the differential grinding in this center-discharge mill, and is 1.53. Similar analysis of Table 9 shows that the -150-mesh material in the feed to the grate mill comprises 1 per cent. of the total weight and contains 3.1 per

Differential grinding is indicated here likewise. Applying the same measure as before, the ratio of assays in the feed is 2.38, in the product 3.48 and the mill index 1.46. Hence there is no substantial difference in the relative action of the two mills toward gangue and friable sulphide.

4. Conical ball mill

One form is shown in Fig. 9. The principal structural difference between this and the center-discharge cylindrical mill is in the shape of the shell. Standard sizes are given in Table 10. This mill was developed from the conception that as the size of the material in the mill diminishes toward the discharge end, the crushing forces should likewise be diminished, and that the cylindro-conical shell would effect such diminution, both by causing a graduated size classification of the grinding media with the largest in the section of greatest diameter, and by graduated variation in the length and character of drop of the balls from parabolic fall of maximum length at the section of greatest diameter to cascade (roll) of minimum length near the discharge trunnion. Size segregation of the crushing bodies is not sharp, but there is distinct concentration of the larger sizes at the longest diameter and *vice versa*, as is shown by Fig. 10 and also by the fact (*124 P 209*) that in changing from a 2-in. to a 4-in. ball load, charging 8 tons of 4-in. balls forced out an equal tonnage of the smallest sizes. Another and, possibly, more important effect of the discharge-end cone is the aid that it affords to egress of ground material. Mills are usually lined in such a way that the inner surface of the cone is ribbed parallel to the mill axis. While the ribs are rising below the pulp level they act as lifters for the pulp and when in a position a short distance above the mill axis they form the lower sides of troughs directed toward the discharge trunnion, down which the lifted pulp flows. This quick-discharge effect is somewhat preferential and makes for rapid discharge of finished material from the mill, thus increasing capacity.

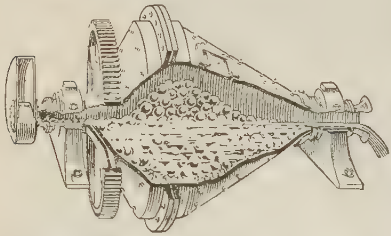

Fig. 9.—Hardinge conical ball mill.

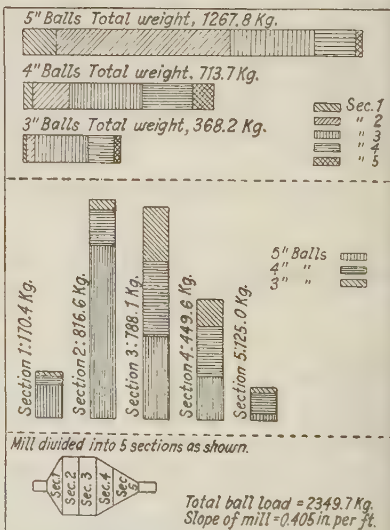

Fig. 10.—Arrangement of balls by sizes in a conical ball mill.

Construction. The shell is usually made of cast iron or cast steel, in two parts, with a tongue-and-groove flanged joint in the cylindrical section. Trunnions are cast integral with these sections and after the flanges have been faced the two parts are bolted together and the trunnions turned down in a lathe. A lighter form of mill is made of riveted boiler plate, with cast trunnions bolted on and then turned down Gears and bearings are similar to those on cylindrical mills (see p. 346). An incidental structural advantage of the conical shape is the fact that it allows a driving pulley to be placed on the pinion shaft between trunnions near the discharge end. This makes for compactness. When, however, the

Performance is shown in Tables 11 and 11a.

[illegible] circuit, to tube-mill feed and consumes 110 hp.

Capacity, according to Table 11, ranges from 30 tons per 24 hr. in a [illegible] mill grinding [illegible] feed in open circuit to [illegible]-mesh to 1015 tons in an [illegible] mill grinding [illegible] feed to [illegible] per cent. on [illegible]-mesh. Power consumption varies from [illegible] hp. per ton of ball load to [illegible] hp., the [illegible] figure corresponding to an undersized of balls. Average for mills of all sizes with normal loads is [illegible] hp. per ton of balls and the range for such mills is not over 2 hp. either side of the average. Tons crushed to table and tube-mill feed sizes, per hp.-hr. consumed, ranges from [illegible] to 0.417, average [illegible]; and from [illegible] to [illegible], average [illegible], in grinding to flotation size.

5. Conical ball mill vs. cylindrical ball mill

At [illegible] Copper Co. a conical mill running side-by-side with a grate mill averaged 250 tons per 24 hr. against 210 tons for the grate mill. Power consumption for the conical mill was 160 hp. and for the grate mill [illegible] hp.; [illegible] tons per horse-power-hour were [illegible] and [illegible] respectively. The conical mill lost much less time and was less sensitive to feed changes. The feed to the grate mill had to be watched continuously and occasionally shut off for 30 minutes or more to allow it to work out of a choked-up condition [illegible] wood chips. There was slightly more fine material in the open-circuit discharge of the grate mill, but the classifier overflows were substantially the

NOTES TO TABLE 11

a Italic numbers refer to column numbers in Table 11*a*. *b* Balls chipped and broke badly. Forged-steel balls substituted, consumption 1.1 lb. per ton. *c* Constant quantity added daily. *d* One man to six 36 × 14-in. rolls, 3 ball mills and 2 drag classifiers. *e* See Fig. 14. *f* Mild-steel plate. *g* Cast-iron and steel plate. *h* Midvale steel. With cast iron, life 58 days; consumption, 1.23 lb per ton. *i* At 17 r.p.m. consumes 92 hp. and has the same capacity. *j* Consumption of chrome-steel balls in mill making 17 r.p.m. is 2.1 lb. per ton. *k* Included with other work. *l* Flexible coupling. Tightening liner bolts. *m* 60 per cent. @ 4-in. and 40 per cent. @ 3-in. *n* Feed is de-slimed sand-table tailing, 23 per cent. +48-mesh; mill discharge, 8 per cent. +48-mesh; classifier overflow, all −48-mesh. *o* Individual liners replaced as worn out. *q* 0.55 lb. consumed, 0.45 lb. waste. *r* Sufficient added each shift to keep ammeter at constant reading. *s* Inspection and re-lining. *t* Cast iron, 120 days, 0.4 lb. per ton; Mn, Cr, life, 300 days. *u Salt Lake Min. Rev., Nov. 15, 1918*. *v* 250 hp. required momentarily at starting. *w* Classifier overflow is 0.5 per cent. +35-mesh, 44 per cent. −150-mesh. *x* Change from 26½ r.p.m. to 17 r.p.m. reduced power consumption from 150 to 100 hp., reduced ball consumption $0.05 per ton of feed, and made corresponding reduction in liner consumption, without affecting grinding. *y* Compare 5 × 10-ft. rod mill at same plant, Table 50. *z* Dimensions inside lining. *aa* Would probably be lower with lower moisture content. *ab* Manganese-steel, wave-type, life 85 days; 23,275 tons ground from −8-mesh to 80 per cent. −65-mesh. Cost of liner, $0.125 per pound f.o.b. factory. Liner flowed and was hard to remove. Forbes-type cast-iron liners, life 88 days, 24,200 tons as above. Cost, $0.0349 per pound f.o.b. concentrator. Re-lining, 4 men, 3 hr. *ac* Has run up to 170. *ad* Compare 6 × 6-ft. grate mill at same plant, Table 5. *ae* In 1920 handled over 200 tons per 24 hr. of crude ore from 7.8 per cent. +1-in. to 3.4 per cent. +48-mesh, but crude is not so hard to grind as this middling. *af* Dropped from 165 hp. by improvement in gear-redu tion set. *ag* Increasing feed rate to 1100 tons on primary mills lowered the amount of −200-mesh in primary-mill discharge to 21.4 per cent. and in the secondary-mill discharge increased the +48-mesh to 3.5 per cent. and decreased the −200-mesh to 47.9 per cent. *ah* In Section 5 one primary and two secondary 8-ft. × 30-in. mills handled 1027 tons from 1.3 per cent. +18.85-mm. to 0.2 per cent. on 48-mesh and 59.4 per cent. −200-mesh with a total power consumption of 360 hp. Ore varies considerably from day to day and this performance is for softer ore than the performance of the 8-ft. × 36-in. mills in Section 6, here give . *ai* Compare 8-ft. × 22-in. pebble mill at Miami, Table 77. *aj* Classifier overflow is 1.8 per cent. +35-mesh, 47.8 per cent. −200-mesh. *ak* Classifier overflow is 0.5 per cent. +20-mesh, 45.7 per cent. −200-mesh. *al* Two mills in series, the first discharging to a Dorr classifier that is in closed circuit with the second. *am* Classifier overflow is 0.6 per cent. +20-mesh, 41.3 per cent. −200-mesh. *an* 0.5 per cent. +100-mesh, and 85 per cent. −200-mesh. *ao* In *22 CMI 98* the product shown in screen test No. 39, Table 11*a*, is given as corresponding to 200 tons per 24 hr. of this same feed. *ap 119 P 808*. *aq* Classifier overflow contains 5.5 per cent. +65-mesh and 73 per cent. −200-mesh. Sands to conical pebble mill. See Table 77. *ar* Shell and feed-end liners, 30,000 tons; discharge-end liner 50,000 to 60,000 tons; total consumption, 0.208 lb. per ton of ore. *as 115 J 398*. *at 123 P 886*. *au* Contains 60 per cent. −200-mesh. *av 101 J 316*. *aw* Weight, 15,200 lb. *ax* 6 per cent. +40-mesh, 35 per cent. −200-mesh. ***CI*** Cast iron. ***CCI*** Chilled cast iron. ***CCr*** Cast chrome steel. ***Cr*** Chrome steel. ***CS*** Cast steel. ***DC***, Dorr classifier. ***FS*** High-carbon forged steel. ***G*** Grease. ***Mang.*** Manganoid. ***Mn*** Manganese steel. ***O*** Oil. ***SS*** Spiral scoop, one-way. ***WB*** Wedge-bar. Cast plates and forged chrome-steel wedge bars.

the basis of comparison used, *viz.*: tons product of a given size per horsepower-hour, the conical mill is clearly superior, particularly in the coarser range. At NEVADA CONSOLIDATED four cylindrical mills and eight conical mills were used in re-grinding −2-mm. classified roll product. Comparative performances are given in Table 13. The product of the conical mill was slightly finer while power and metal consumption were distinctly less.

Table 13. Comparative performances of conical and cylindrical ball mills at Nevada Consolidated

	Cylindrical	Conical
Size of mill	7×6-ft.	8-ft.×30-in.
Feed rate, dry tons per 24 hr., average	359	451
Moisture, per cent	27.9	26.9

a Cast-iron liner plates, chrome-steel lifting bars, cast-iron balls.

6. Mechanics of the ball mill

Davis (*61 A 250*) gives an exhaustive mathematical analysis of the action in a ball mill. A summary of his conclusions follows:

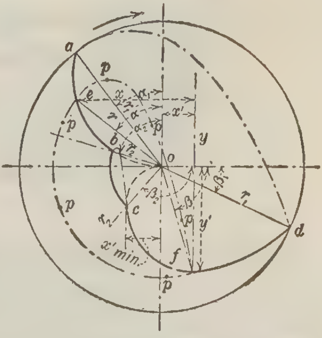

FIG. 11.—Chart of theoretical paths of balls in a ball mill (*after Davis*).

Notation: (See Fig. 11) r = radius in ft., drawn to any particle p at the instant that its path changes from circular, under the impulse of the mill shell, to parabolic under the influence of its acquired momentum and gravity, or *vice versa*. r_1 = radius of mill drawn to the point where the outer layer of balls changes from circular to parabolic motion or *vice versa*. r_2 = radius drawn to the point of motion change of the inner layer of that part of the charge which, at any given instant, is following a circular path. R = radius of gyration of charge near line aO. α = angle in degrees between vertical and the radius r drawn to the point of change from circular to parabolic motion. α_1 = angle between vertical and the corresponding radius r_1. α_2 = angle between vertical and the corresponding radius r_2. α_R = angle between vertical and R. β = angle

between horizontal and the radius r drawn to the point of change from parabolic to circular motion. β_1 = angle between horizontal and corresponding radius r_1. β_2 = angle between horizontal and corresp nding radius r_2. n = speed of mill in rev. per sec. N = speed of mill in r.p.m. N_1 = critical speed of mill in r.p.m. V_b = velocity of particle relative to striking point. w = weight of any given portion of charge, *e.g.*, one ball, in lb. W = weight of entire charge in lb. P = fraction of mill volume occupied by charge (voids included). g = acceleration due to gravity = 32.2 ft. per sec. per sec. k = a constant for any given mill speed $= 4\pi^2n^2/g = 1.226n^2$. K = a constant $= r_2/r_1$. H = height of charge in mill at rest, in ft. E = Kinetic energy in ft.-lb. T = time for a ball to complete one cycle, in sec. T_r = time for one rev. of mill, in sec. C_n = cycles of ball travel per rev. r_c = radius of circular arc aO along which change from circular to parabolic motion occurs. x, y, See Fig. 11.

Equations:

$$\cos\alpha = kr = 1.226rn^2, \quad (1) \qquad r_c = \frac{0.408}{n^2}, \quad (2)$$

$$\cos\alpha_R = 0.867r_1n^2\sqrt{1+K^2}, \quad (3) \qquad N_1 = \frac{54.19}{\sqrt{r_1}}, \quad (4)$$

$$y = x\tan\alpha - \frac{0.613n^2x^2}{\cos^4\alpha}, \quad (5) \qquad \beta = 3\alpha - 90^\circ, \quad (6)$$

$$V_b^2 = 16rg\cos\alpha\sin^4\alpha. \quad (7)$$

For the best theoretical efficiency

$$V_{b\,\text{max.}} = \frac{7.88}{n}, \quad (8) \qquad V_{b\,\text{min.}} = \sqrt{16Kr_1g\cos\alpha_2\sin^4\alpha_2}, \quad (9)$$

$$\alpha_R = 54^\circ\,44', \quad (10) \qquad K = \sqrt{\frac{0.443}{r_1^2n^4} - 1}, \quad (11)$$

$$N = \frac{48.95}{\sqrt{r_1}\sqrt[4]{1+K^2}}, \quad (12) \qquad \cos\alpha = \frac{0.8165r}{r_1\sqrt{1+K^2}}, \quad (13)$$

$$\cos\alpha_1 = \frac{0.8165}{\sqrt{1+K^2}}, \quad (14) \qquad \cos\alpha_2 = K\cos\alpha_1, \quad (15)$$

$$C_n = \frac{T_r}{T} = 1.444 \text{ (considering all balls to have the same cycle as if their radius of revolution were the radius of gyration)}. \quad (16)$$

$$K = -0.024 + 0.39\sqrt{7 - 10P} \text{ (very nearly)}, \quad (17)$$

$$\text{HP.} = Wr_1^{\frac{3}{2}}\left[0.004467\frac{1-K^3}{(1+K^2)^{\frac{1}{8}}} - 0.0037\frac{1-K^5}{(1+K^2)^{\frac{3}{8}}} + 0.00088\frac{1-K^7}{(1+K^2)^{\frac{5}{8}}}\right] \quad (18)$$

$$r_2 = Kr_1. \quad (19)$$

Examples of application of Davis' equations. An 8 × 6-ft cylindrical mill charged with 28,000 lb. of steel balls. Assuming 35 per cent. of voids in the ball charge, the weight per cu. ft. of charge is 325 lb. and the volume of the charge, 28,000/325 = 86 cu. ft. The interior volume of a 8 × 6-ft. mill is 301 cu. ft. (according to Davis. This figure is based on the assumption of 8 × 6-ft. inside. The actual internal volume of an 8 × 6-ft. mill is probably 20 per cent. less than this on account of the space occupied by the liners), hence the charge occupies 86/301 = 28.6 per cent. of volume = P. Then from equation (17), K = 0.770; from equation (12), the best speed = N = 21.8 r.p.m.; and from equation (18), HP = 153. (This is low for an 8 × 6-ft. mill.) If 8000 to 10,000 lb. is added for

the weight of the pulp and W is made the total load in mill = 36,000 to 38,000 lb., HP becomes 197 to 208, which is about correct (see Table 4). From equation (14), $\alpha_1 = 49°$ $30'$ and from equation (15), $\alpha_2 = 60° 20'$. From equation (19), $r_2 = 3.05$ ft. By equation (6), $\beta_1 = 58° 30'$ and $\beta_2 = 91°$. Values of r for values of α between α_1 and α_2 may be obtained from equation (1) and for values of β between β_1 and β_2 from (6) and (1). By plotting these values, curves $a - b$ and $c - d$ in Fig. 11 may be obtained. Then the concentric circular arcs represent the circular paths of the balls and the parabolas the free-moving paths. The value of r for the start and finish of any particle on its parabolic path is the same. The equation of the parabolic path of any given particle, taking its point of starting on the parabolic path as origin of co-ordinates, is given by equation (5). Thus the complete theoretical path of the ball charge can be plotted as in Fig. 12.

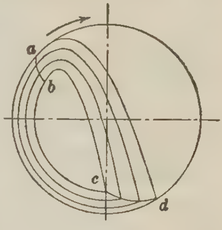

Fig. 12.—Chart of ball paths in 8 x 6-ft. mill at 21.8 r.p.m. with 28,000-lb. ball (*after Davis*).

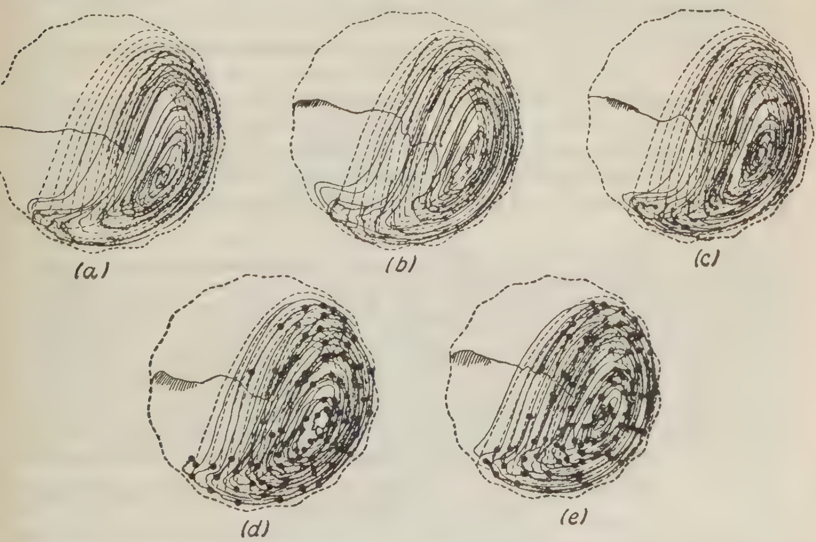
Haultain and Dyer (*69 A 198*) question Davis' conclusions as to ball paths on the basis of a remarkable set of moving pictures portraying the performance in a glass-ended cylinder 2 ft. diam. by 2½ in. long, but Davis' discussion of their results confirms his original conclusions. Fig. 13 shows five different conditions of operation graphically summarized by Davis from the films. The dash lines in the figures are the theoretical paths. The lines carrying round black dots represent actual paths of individual balls as traced from the films. In Figs. 13*a* and 13*d*



a. Small balls, no rock. *b*. Small balls, some quartz. *c*. Small balls, full charge of quartz. *d*. Large balls, no rock. *e*. Large balls, full charge of quartz.

Fig. 13.—Actual ball paths in tube mills.

departure of the actual paths from the theoretical is greatest. In these operations balls and water only were present, and the discrepancy is due to slip between ball load and lining, amounting to 8 to 10 per cent., resulting in failure to carry balls to their full theoretical height. This slip eliminated

practically all free fall in Fig. 13*a*, and materially decreased the amount of free fall in Fig. 13*d*. But in Figs 13*c* and 13*e* sand (corresponding to ore) was present, slip was practically zero, and the actual paths approximated the theoretical very closely.

7. Wear of balls and liners

General. Wear depends primarily upon the materials of which balls and liners are made. With given ball and liner material the wear is, of course, greater with hard than with soft ore; it is usually greater with fine feed than with coarse, although this is undoubtedly because fine feed connotes fine product while coarse feed does not necessarily do so. (If material is to be finished to the same size, wear is greater for coarse than for fine feed.) Wear increases with increase in mill speed and with increase in moisture content in the mill, and it is greater for open-circuit than for closed-circuit crushing (per ton of original mill feed), when the endeavor is to finish to the same size in both cases.

Ball wear. The most resistant material in common use for balls is forged chrome steel. Wear of chrome-steel balls with ordinary ores is from 1 to 2 lb. per ton grinding from 1.5- or 2-in. to 20- to 48-mesh, closed-circuit, and from 0.5 to 1.5 lb. per ton grinding from the same feed size to 6- to 10-mesh, open circuit. Corresponding figures for forged high-carbon steel balls are 1.5 to 3 lb., closed-circuit, and 1 to 2 lb., open-circuit.

At Engels C. M. Co. the consumption of forged- and chrome-steel balls under similar conditions was 3.2 and 1.9 lb. per ton, respectively.

Consumption of cast-iron balls is usually from 1.5 to 2 times that of forged steel, if the balls are 2-in. or smaller; large balls are excessively consumed due to breakage. Manganoid and Duraloid (cast manganese-steel) balls wear about the same as forged high-carbon steel and are cheaper. They break readily, however, and are not likely to be economical when large sizes are necessary.

At Utah Leasing Co. the consumption of 2½-in. Duraloid balls in an 8-ft. × 30-in. conical mill was 2.19 lb. per ton (cost $0.1018 per ton). At Miami Copper Co. the consumption of 2-in. chrome-steel balls in 8-ft. × 36-in. conical re-grinding mills was 0.8015 lb. per ton for the year 1916. With manganoid balls of the same size in the same service, consumption was 1.1928 lb. per ton. Prices were $0.05 and $0.025 per lb., respectively. At United Eastern (*63 A 556*) 1½-in. chrome-steel balls in fine-grinding service (20-mesh to 85 per cent. −200-mesh) were consumed at the rate of 3.18 lb. per ton while cast-iron balls the same size wore at the rate of 4.35 lb. per ton. At Inspiration (1916) the wear of chrome-steel balls making 8-mesh product, open circuit, in Marcy mills was 0.3 to 0.7 lb. per ton; making 48-mesh product in closed circuit the wear was 1.7 lb. per ton (1.82 lb. in 1918). Table 14 gives comparative data on consumption of chrome-steel, forged-steel and

Table 14. Comparison of manganoid and chrome-steel balls in 8 × 6-ft. Marcy mills at Inspiration; 1920; 44-day run

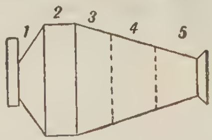
Material	Manganoid	Chrome steel
Diameter of balls, in.	4½	4
Consumption, pounds per ton	3.164	1.66
Cost of balls, cents per pound	4.54	5.15
Cost of balls, cents per ton ground	14.36	8.55

Comparative consumption of chrome-steel and forged high-carbon steel balls over a one-year period was: Chrome-steel, 1.75 lb. per ton; forged-steel, 1.82 lb.

manganoid balls at the same plant. At Anaconda consumption of cast-iron balls in a 7½-ft. × 72-in. (inside lining) mill was 5.5 lb. per ton at 23 r.p.m. and 2.75 lb. at 15 r.p.m. At Nevada Consolidated consumption of 3-in. machine-cast balls (Nov., 1923) was 1.74 lb. per ton; 3-in. sand-cast, 1.83 lb.; 2-in. drop-forged steel, 1.0 lb.

Size of balls has a small effect on ball wear. In 5 × 6-ft. ball-pebble mills at United Eastern (*63 A 556*), grinding from 20-mesh to 85 per cent. − 200-mesh, the consumption of 2-in. chrome-steel balls was 3.00 lb. per ton and of 1½-in. was 3.18 lb. per ton. At St. Joseph Lead Co. (*66 A 107*) consumption of cast-iron balls in a 6-ft. × 22-in. conical mill crushing to 10-mesh was 1.218 lb. per ton and of steel balls of substantially the same size (1.5- to 2.5-in.), 0.332 lb. In the same mill the wear of 5- to 2.5-in. steel balls was only 0.12 lb. per ton.

Liner wear varies with liner material, position of liner, kind of ore, tonnage, size of feed and product, whether open- or closed-circuit grinding, ball load, speed, and pulp consistency. Life of liners ranges from 4 months to 3 years but the average for all kinds of liners is close to 6 months. Consumption of manganese-steel liners, which are most commonly used, averages (from Tables 4, 5 and 11) 0.35 lb. per ton when grinding to sizes between 6- and 20-mesh, mostly in open circuit, and 0.50 lb. per ton in grinding in closed circuit to flotation size. Chrome-steel liners are more resistant, if the averages based on the meager data in Table 5 are dependable, the consumption being 0.18 lb. per ton in coarse grinding and 0.39 lb. per ton in fine grinding. Cast-iron liners are least resistant, the wear in coarse grinding averaging 0.69 lb. per ton. Comparative consumption of different metals on the same ore is given in note *g* Table 4, and note *t*, Table 11. Wear on liners in different parts of the mill is shown by Fig. 14; note *ar*, Table 11; note *w*, Table 5; and by Table 15. A considerable part of the liner consumption is scrap, hence the heavier the new liner, the smaller the proportion of waste rejected. At United Eastern (Table 15) rejection averaged 43 to 45 per cent. of the new weight of all liners. Progress is in the direction of heavier liners. It is commonly stated and probably true that the consumption on hard ore is greater than on soft, but comparative data on this score, uncomplicated by variability in other factors, are not available in Tables 4, 5 and 11. It is, of course, true that the abrasive character of the hard ore is the greater and that, on account of slower crushing rate, more motion of the liner with respect to the load is necessary per ton of hard ore ground, hence on both grounds more wear is to be expected. Life of a liner will decrease with increase in mill tonnage rate but consumption per ton of ore will generally decrease on account of the increased cushioning effect of the greater tonnage. Wear is usually greater with coarse than with fine feed, as is indicated by the greater wear of liners near the inlet end of a center-discharge cylindrical mill. This effect may be obscured in a peripheral-discharge mill running with thin feed and low pulp level by excessive wear near the grate occasioned by lack of pulp to cushion the ball charge. Wear is distinctly greater in fine closed-circuit grinding than in coarse open-circuit work as shown by the comparative figures



Number	Life	Tons ground	Number of pieces
1	10 mo	45 000	16
2	8 mo.	36 000	16
3	9 mo.	40 000	13
4	1–3 yr.	....	12
5	Indefinitely long	......	8

Fig. 14.—Liner wear in conical ball mill at Bunker Hill and Sullivan Mining Co.

on wear of manganese-steel liners previously cited (0.50 and 0.35 lb. per ton of feed, respectively). Liner wear is greater with a heavy ball load than with a light load and, all other things being equal, greater with large balls than with small. Probably the best evidence of this fact, complicated, it is true, by the fact that the size of feed is different in the different places, is the comparative wear in the different sections of the conical mill, shown in Fig. 14. Wear increases with increase of speed and with increase in moisture content of the pulp.

At Wright-Hargreaves (115 *J* 881) the wear in an 8-ft. × 30-in. conical mill was excessive at 22 r.p.m., when the feed rate was 200 tons per day, open-circuit, but fell to normal when the speed was reduced to 19½ r.p.m. At Nevada Consolidated (see Table 11) the wear of cast-iron balls (which is proportional to liner wear) was 1.55 lb. per ton in an 8-ft. mill at 28 r.p.m. and 1.34 lb. per ton at 24½ r.p.m.

Table 15. Liner wear in ball mills at United Eastern. (*After North*)

Liner	Material	Consumption, pounds per ton (including scrap)	Per cent scrap	Cost per ton milled (1917, 8)
		No. 64½ Marcy		
Feed-end	Manganese steel	0.072	32.2	$0.0110
Shell (step type)	Manganese steel	0.163	45.5	0.0268

Bolts, clamp bars, center liners, etc.		0.022	63.8	0.0068
Total		0.312	43	$0.0583
		5 × 6-ft. ball-peb mills		
Feed-end	Chrome steel	0.040	52	$0.0072
Throat	Chrome steel	0.007	40	0.0012
Shell	Chrome steel	0.115	28	0.0218
Discharge grates	Tool steel	0.005	40	0.0014
Discharge wedges	Chrome steel	0.017	41	0.0031
Total		0.184	45	$0.0347

Liner wear must be watched carefully in order to insure that the shell is not reached and perforated. With bolted liners the plates usually break when too thin, which allows the bolt to loosen and causes leakage, thus giving warning. At many plants mills are stopped periodically for inspection. At some plants, *e.g.*, United Eastern (65 A 557), after a wear record has been established, the mill is stopped and opened only when records of past performances show that a particular part of the liner should be reaching the danger point.

Cost of maintenance. The cost of balls and liners is 80 to 90 per cent. of the total maintenance cost of ball mills. The following figures for a 4 × 3½-ft. Marcy mill at Elko Prince (1916–1918 incl.) are typical of the distribution. Total maintenance, $0.2460; liner, $0.1042 (= 42.5 per cent.); balls, $0.1011 (= 41.0 per cent.); miscellaneous supplies, $0.0253 (= 10.3 per cent.); labor, $0.0154 (= 6.2 per cent.).

8. Operation of ball mills

Capacity. The meaning of the word capacity is not closely defined in the literature of cylinder mills. The ability of a mill without grates to pass material from inlet to outlet is limited only by the ability of the feeding device to force the material into the mill. The mill will reduce the average size of the material passing through it, more or less, depending upon the rate of passage and also upon a number of other factors such as nature of material ground, size of feed, size of product required, percentage of solids in feed, type of liner, size of balls, weight of charge, speed of mill, and whether or not in closed circuit with a classifier. With grate mills the grate openings also affect capacity. Probably the best method of stating capacity is in terms of tons of material of the desired maximum size and smaller actually produced by the mill per unit of time. Tables 16 and 17, generalized from operating

data and manufacturers' catalogs, give figures that are reliable for estimating purposes for ordinary ores. For hard and tough ores the capacity may be reduced 50 per cent.; with soft, decomposed feed the figures can be increased somewhat. Decrease in size of feed will cause an increase in capacity, greater the smaller the diameter of the mill.

Rate of feed to mill. In open-circuit grinding the amount of material of any given size produced by a single mill increases with the rate of feed. (See Table 18 and Fig. 15.) Production passes through a maximum which is reached more quickly the finer the desired size. (See Tables 19 and 20.) On the other hand, the amount of oversize discharged likewise increases with increase in the feed rate and, since the object of the grinding operation is to reduce all of the material to the limiting size, high-capacity open-circuit work is justifiable only when, taken in conjunction with the finishing grinding, a lower cost per ton of finished product is attained than is otherwise possible. If the feed rate in open-circuit grinding is cut down to the point where the discharge is all of a desired fine size, capacity, particularly in connection with power consumption (tons per horsepower-hour) is extravagantly low, consumption of grinding media is high, and wear of lining at the discharge end of the mill is excessive. Much of the material must be over-ground to insure

that all is sufficiently ground. Hence in order to take advantage of the ability of a cylinder mill to handle large tonnages and produce therefrom a large amount of finished product per unit of power, the mills are run in closed circuit with a sizing device that returns oversize to the mill feed. The effect of closed-circuit crushing is clearly shown, by comparison of Table 18 with Table 21, to be to increase the amount of −200-mesh material produced per horsepower-hour at all tonnages throughout the common range of the two experiments.

At Tough Oakes (*101 J 691*) a conical ball mill run open-circuit to produce tube-mill feed was fitted with a double-cone screen in the discharge trunnion, the converging part

of this screen being a continuation of the surface of the discharge-end cone of the mill, so that the level at which coarse material could discharge was raised. The ball load could be and was increased from 8500 to 11,500 lb. Oversize was returned to the head of the mill by belt conveyor. Capacity was increased from 82.7 to 102.3 tons per 24 hr., power decreased from 40 to 35 hp., tons per hp.-hr. increased from 0.086 to 0.119, and ball consumption decreased from 2.45 to 1.80 lb. per ton.

a Iron ore, 35 per cent. magnetite, balance quartzite and silicates; all through 0.25-in. screen. 40 per cent. moisture, 23.8 r.p.m., 28,000 lb. @ 3- and 2-in. balls.

It is not to be understood, however, that closed-circuit grinding to a given size is always more economical than open-circuit. In the first place, tests in Tables 18 and 21 do not give a true comparison, if the ordinary mean-

ing of the term closed-circuit is taken, because the material was not all finished to the size taken as the basis for comparison in either the closed-circuit or open-circuit tests. Had it been, it is apparent that the tons produced per horsepower-hour would have been considerably reduced, particularly in the tests at the higher tonnages, in which the percentage of final oversize was large. At these tonnages, therefore, the production of −200-mesh material per unit of power would have been greater in the open-circuit work. This discrepancy becomes larger the coarser the feed and leads to stage reduction.

Truscott recommends feeding coarse material to short ball mills at such a rate (in a 50 per cent. pulp) that the available volume (which he takes as the mill volume below overflow level minus the ball volume) is re-filled every 1 to 2 min. This figure accords reasonably with good practice when the ball load is all that an open-trunnion mill will stand, but applied generally it would call for a higher feed rate to an undercharged mill than to one with full charge, which, of course, should not be the case.

Stage-reduction. Whenever ball-mill feed is coarser than 0.75-in. maximum size, or, with even finer feed than this, when the tonnage to be crushed is sufficient to require more than one mill, crushing will usually be cheaper if the reduction is done in two or three stages. In such work usually only the final mill is run in closed circuit and in the other mills advantage is taken of the ability to handle large tonnages and produce, in connection, it is true, with a large percentage of over-size, a large tonnage of finished product per unit of power expended.

Tables 22 and 23 present the results of a test comparing one- and two-stage crushing of −0.25-in. iron ore to 100-mesh (*Davis, 61 A 253*), both mills being in closed circuit. In

Table 22. Performance of 8-ft. × 22-in. conical ball mill crushing from 0.25-i to 100-mesh in one step. (*After Davis*)

Closed circuit with Dorr classifier. Original feed, 177 tons per 24 hr., return, 792 tons; total 969 tons. 28,000 lb. @ 2⅜-in. and 2-in. balls. 23.8 r.p.m. 30 per cent. moisture. 145 hp.

the single-stage operation the final product contained 1.4 per cent. oversize on the limiting screen against 2.4 per cent. in the two-stage treatment. Considering both products satisfactory, single-stage crushing produced finished material at the rate of 177 tons per 24 hr. or 0.049 ton per hp.-hr. In the 2-stage operation −100-mesh material was produced in the first stage at the rate of 294 tons per 24 hr. or 0.085 ton per hp.-hr. In the second stage finished material was produced at the rate of 157 tons per 24 hr. or 0.045 ton per hp.-hr., which is nearly as good as was done in the single-stage operation, yet Davis states that this second mill was distinctly underloaded and estimates that it could have produced 230 tons of finished material per 24 hr. which would have been 0.066 ton per hp.-hr. As it was, the 2-stage operation as a whole produced 368 tons of finished material per 24 hr. or 0.053 ton per hp.-hr.

Table 23. Performance of 8-ft. × 22-in. conical ball mill crushing from 0.25-in. to 100-mesh in two steps. (*After Davis*)

FIRST STAGE: Closed circuit with Dorr classifier. Original feed, 368 tons per 24 hr.; return, 768 tons; total, 1136 tons. 28,000 lb. @ 3- and 2-in. balls; 23.8 r.p.m.; 145 hp.

SECOND STAGE: Closed circuit with Dorr classifier. Original feed, 157 tons per 24 hr.; return, 120 tons; total, 277 tons. 28,000 lb. @ 2- and 1-in. balls; 23.8 r.p.m.; 145 hp.

The performance of 8-ft. × 36-in. conical ball mills at MIAMI (Table 11) is a good example of the economy of 2-stage grinding with one primary mill in open circuit followed by two secondary closed-circuit mills in parallel. The capacity of the three mills as arranged was 967 tons per 24 hr. from 0.4 per cent. on 1-in. to 0.1 per cent. on 48-mesh, or 0.079 ton per hp.-hr. Their capacity in parallel on 3-mesh feed was 822 tons per 24 hr. to the same size, or 0.068 ton per hp.-hr. The capacity of the three mills treating primary feed (test 22, Table 11) in closed circuit would have been less than this because the primary feed was coarser. The primary mill in open circuit produced 304 tons per 24 hr. of −48-mesh material, or 0.093 ton per hp.-hr. against 237 tons each (0.068 ton per hp.-hr.) in the secondary mills in closed circuit.

North (*63 A 554*), commenting on the UNITED EASTERN flow-sheet, states that 2-stage ball milling is about 15 per cent. cheaper than stamps plus tube mills in the district and that single-stage ball milling shows about the same supply and labor costs as 2-stage, but about 20 per cent. greater power consumption.

Circulating tonnage in closed-circuit crushing ranges from 50 to upwards of 500 per cent. of the original feed tonnage. The average return is between 150 and 200 per cent. of the original. A greater percentage would ordinarily overload the classifier.

At the MESABI IRON CO., the experimental flow-sheet was arranged to permit the use of one to four Dorr classifiers with one 8-ft. × 22-in. conical ball mill. Results of a test run are shown in Table 24; they show distinct increase in capacity and fineness with increase in number of classifiers. Against this advantage, however, must be balanced a decided inconvenience in handling the circulating load and a much larger floor space devoted to grinding; as a result multiplication of classifiers has not yet been adopted in grinding practice.

Nature of material ground has a marked effect on ball-mill grinding in the case of certain materials, comparing, *e.g.*, coal, cement copper, gypsum, cocoanut shells, ores, brass ashes, etc., but considering ores alone, the physical character has much less effect on the amount of crushing done than operating factors such as size of feed, moisture content, ball load, etc. Thus in Table 4, comparing the 6 × 4-ft. mill at ST. JOSEPH LEAD CO. with the 6 × 6-ft. mill at CONSOLIDATED ARIZONA SMELTING CO., dolomite gangue appears to grind from 3- to 8-mesh much more readily, based on tons per horsepower-hour,

than quartzitic rock from 2- to 4-mesh, and this is in line with the reasonable expectation that limestone is more easily ground than quartz. On the other hand, substantially the same amount of −200-mesh material was produced by both mills, at the rate of 0.034 ton per hp.-hr. from dolomite and 0.033 ton from quartz. In Table 5, comparing the 6 × 4½-ft. mills at United Eastern and Shattuck Arizona, the quartzitic ore at United Eastern is crushed from 2.5-in. to 4-mesh at a higher rate per horsepower-hour than Shattuck Arizona limestone is crushed from 0.5-in. to 3-mesh and −200-mesh material is produced from the quartz ore at the rate of 0.024 ton per hp.-hr. against

a rate of 0.020 ton from the limestone. The same conclusion is indicated by Table 25, compiled from Lennox' work (*61 A 237*). The column "Comparative grinding resistance" (as given by Lennox) indicates but little difference between a number of ores in the middle range, and when the "Grinding order," which is based on another method of analysis of the same data, is compared with this column, it is seen that this more direct method of weighting the results causes marked changes in Lennox' estimate of the ease of grinding the different materials. Thus while, *e.g.*, by both methods of estimating, ores 34 and 13 fall together and likewise ores 18 and 20, yet Lennox' method makes the first two slightly more resistant than the second two while the other separates the two pairs a considerable distance in the scale and indicates that 18 and 20 are much more resistant than 34 and 13. Both methods agree in placing ores like 28 and 11 at one end of the scale and 22, 32, 30 and 48 at the other and experience accords with the conclusion thus pointed, *viz.*: that there are certain ores so very hard and tough that they are ground with

much more difficulty than the average and certain others that are easier to grind than the average. It would not be safe to take more than 50 to 75 per cent. of the capacity figures in Tables 16 and 17 for the first type of ore, and 150 to 200 per cent. can safely be taken for the second, but no distinct difference in ease of grinding should be expected between, say, ores 44 and 42 notwithstanding they appear widely separated in the table.

(*After Lennox.*) *c* Numerical order of increasing "grindability" of corresponding samples, as indicated by increasing amounts passing the 200-, 65- and 20-mesh and decreasing amounts remaining on a 10-mesh screen in the products obtained by 5- and 10-min. batch-crushing tests on a standard feed in a small ball mill.

Such differences as do exist are more marked in grinding to very fine sizes than in the coarser range. Thus Young's work (*58 A 126*), summarized in Table 26, shows little difference in the amount of −48-mesh material produced

Table 26. Effect of nature of feed on capacity of ball mill(*a*)

a Feed rate in both runs, 18 tons per 24 hr. Moisture, 36 per cent.

from trap and quartzite under similar conditions, but does show a distinct difference in the amount of −200-mesh product. Hanson (*120 P 17*) classes Inspiration ore (which is the same as Miami ore, sample No. 16, Table 25) as a soft ore and warns that the capacities there attained in an 8 × 6-ft. grate

mill (475 tons per 24 hr. from 4.7 per cent. +1.5-in. to 0.6 per cent. on 48-mesh) are not to be expected on harder ores.

Size of feed ranges in practice from 3- or 4-in. maximum size down to, say, 20-mesh (see Tables 4, 5 and 11). For any given ball mill and ball charge there is probably a feed size that will give, in connection with the preceding crushers, maximum tonnage of a given desired size per horsepower-hour, but what this size is is rarely, if ever, worked out exhaustively in a plant. Too frequently it is not examined into at all, but the ball mill is set the task of handling a given feed whose size is determined by other and often less important considerations than the resulting efficiency of the mill. The problem is dodged so frequently on account of the difficulty of obtaining convincing evidence.

The classic dissimilarity in practice lies between Miami Copper Co. and Inspiration. These are adjoining mines with similar ores that enter the coarse-crushing plant at about the same maximum size, *viz.*: 18-in., and are ground to substantially the same size (48-mesh) for flotation. At Inspiration, crusher product, 3- or 4-in. maximum size, goes directly to 8 × 6-ft. grate mills; at Miami 8-ft. × 36-in. conical mills are fed with −¾-in. roll product. Table 27, compiled from the booklet issued by Miami Copper Co., at the time

a Reckoning Inspiration on the same basis as Miami, viz., 1.1¢ per kw.-hr. *b* With power cost raised as above this would be higher. *c* For April, 1917, grinding was to 3 per cent. + 48-mesh.

of the Arizona meeting of the A.I.M.E., 1916, and from a report of Inspiration operations (*102 J 678*) and from miscellaneous notes, shows the essential results at the two mills. It indicates a distinct advantage either for the finer feed at Miami or for the conical mill or both. The extreme in roll reduction prior to ball milling is found at Canada Copper Corp., where roll crushing is carried to 10-mesh, followed by 2-stage ball milling to 100-mesh. At Engels (*123 P 189*) an 8 × 6-ft. Marcy mill and one 6 × 12-ft. tube mill in series handled −2-in. feed to flotation size at the rate of 444 tons per 24 hr. Total power consumed was 377 hp. so that the tonnage ground per hp.-hr. was 0.049. With −1-in. feed the ball mill followed by two tube mills in parallel handled 866 tons per 24 hr. with 519 hp. or 0.069 ton per hp.-hr. Not over 75 hp. would be required to break the +1-in. material in this feed to −1-in., which would make the tons per hp.-hr. from 2-in. 0.061 by the stage operation. At Consolidated Arizona Smelting Co. (*104 J 71*) a 6-ft. cylindrical mill and a 6-ft. conical mill installed to grind to 8-mesh in open circuit utterly failed to deliver

the expected tonnage with −1.5-in. feed. Many ⅜-in. to ½-in. pebbles were discharged. Reducing feed to −1-in. increased tonnage considerably. Further decrease to −0.75-in. doubled the capacity over that on −1-in. feed. Lay (*114 J 1123*), commenting on the performance of the 5 × 4-ft. center-discharge mills at Le Roi No. 2 (see Table 4), says that further reduction of the primary-mill feed (−1.5-in.) is clearly indicated.

The present-day trend is toward finer initial feed to primary ball mills and toward stage ball or tube milling, except in the cases where limited tonnage will not justify the more elaborate equipment.

Size of product is the most important factor in determining capacity of a ball mill. Tons per horsepower-hour, based on Tables 4, 5 and 11 average 0.200 for mills delivering 8-mesh and coarser products, 0.146 for mills delivering at 10- to 20-mesh, 0.090 when grinding to between 28- and 48-mesh, and 0.080 when grinding to 65-mesh and finer.

Moisture. Changes in moisture content of the pulp in a ball mill affect its grinding capacity in several different ways and the net result is not invariably susceptible of correct prediction. The moisture content affects the fluidity of the pulp and also its transporting power. Perfectly dry rock, when ground fine, is surprisingly fluid, flows readily through a cylinder mill, and has great transporting power. Its fluidity is evidenced by the fact that it readily discharges from a mill with horizontal axis; its high transporting power is illustrated by the large particles in the discharge (see Table 28). When the moisture content is between 8 and 15 per cent., or thereabouts, especially if the solid contains clayey matter, a stiff mud is formed that cannot be forced through the mill and effectually prevents operation. With upwards of 20 per cent. moisture, ordinary pulps are sufficiently fluid to pass readily through the mill, the fluidity increasing with increase in moisture content. For a given moisture content the apparent wetness is greater the coarser the solid particles. In such wet pulps varying moisture content has different and somewhat contradictory effects on the performance of a mill. In the first place the transporting power of the pulp increases with the decrease in moisture content (see Sec. 20, Art. 10), hence, all other things being equal, the thicker the pulp the larger the largest particles arriving at the discharge end of the mill. In the center-discharge types these coarse particles appear in the discharged products, but in a grate mill the thick, coarse pulp is held back by the grate. Hence from this one standpoint, a thick pulp will cause the production of large oversize

in a center-discharge mill, while in a grate mill it will result in reduction in the amount of coarse oversize. Conversely, increased dilution will produce a more granular discharge from a grate mill while it may result in increased fineness in the discharge from a center-discharge mill (see Table 29).

At Asturiana de Minas (*115 J 396*) when a 4.9-ft. (diam.) conical mill with 2-ton ball load was fed with −2-in. feed at the rate of 50 tons per 24 hr., the product with 30 per cent. moisture in the mill contained 1 per cent. +2-mm., 83 per cent. −40-mesh, and 17 per cent. −200-mesh; while with 50 per cent. moisture the corresponding quantities were trace, 92 and 28 per cent. The experimenter found that increase in moisture to 80 per cent. caused further increase in fineness of discharge and that progressive thickening below 30 per cent. moisture caused production of a progressively coarser product until grinding ceased altogether. At Catemu (*123 P 886*) a 4½-ft. × 16-in. conical mill (see Table 11) was operated at from 20 to 60 per cent. moisture. The best results were obtained at about 35 per cent. with soft, clayey ore and 30 per cent. with hard, compact ore. When moisture dropped below 30 per cent. the mill discharged much coarse material.

From another standpoint thick pulp will tend to increase the tonnage of fine material produced in both types of mill. This follows from a consideration of the behavior of thick and of dilute pulps at the ball surfaces. With a thick pulp all of the balls in the mill are coated with a layer of solid all the time, whether they are above or below the general pulp level in the mill, and, therefore, every impact and every relative movement of balls in contact will result in crushing, provided only that the balls are heavy enough. With dilute pulp, on the other hand, the balls above the general pulp surface are substantially free of pulp and little grinding takes place in this part of the load; also the concentration of solid per unit of volume is less below the pulp surface, and hence the crushing done for any given relative ball movement tends to be less. On the other side of this picture, however, is the fact that the cushioning effect of dilute pulps is not so great as that of thick pulps and hence the loss in momentum of falling balls after striking the pulp surface is not so great in dilute pulps. Finally, the volume of pulp corresponding to a given tonnage of solid matter is greater for dilute than for thick pulps and with equal tonnages of solid passing through the mill the rate of passage is higher with the dilute pulp and less opportunities to be crushed are, therefore, afforded. The usual result of this combination of effects is to increase the tonnage of fine material produced by decreasing the moisture content and simultaneously increasing the tonnage of solid passed through the mill. The point of maximum grinding efficiency (maximum tonnage of desired product per mill per day) is found in most cases to lie between 25 and 35 per cent.

moisture for coarse feeds (0.5 in. maximum and upwards) and between 30 and 50 per cent. moisture for finer feeds. Table 30 (*66 A 105*) shows in detail results in accord with this conclusion. Table 29 (*58 A 126*) shows the less common but nevertheless not exceptional case. Table 29 shows also that the power consumption per mill is higher with high moisture content than with low. Thick pulp crowds the ball charge toward the mill axis and lessens the lever arm of the load.

In most cases water is added to the mill to bring pulp to the proper consistency. Commonly this water is necessary to make the classifier-sand return flow in the launder. Dowsett (*108 J 185*) recommends that, in conical mills, at least, as much of the new water as possible be added from the discharge end about 1½ to 2 ft. back in the discharge cone. This increases the fluidity of the pulp in this part of the mill and lessens discharge of oversize.

Wet *vs.* dry grinding. All wet-concentrating mills grind wet but many industrial plants grind dry. Capacity, power consumption, and ball (or pebble) and liner wear are greater in wet than in dry grinding. Wet grinding permits more efficient closed-circuit work for all fine sizes (less than 10-mesh) than dry and has the added advantage that it eliminates dust troubles. Hardinge (*114 J 935*) limits the capacity increase in wet grinding to 15 to 25 per cent. and states that pebble and liner wear are less than half as great in dry grinding, and capital cost less, but even so believes that wet grinding is cheaper on account of the greater efficiency of the wet closed circuit.

Liners with rough surfaces produce more tumbling action of balls

than smooth-surfaced liners and therefore are better for coarse and intermediate grinding; but for finest grinding, experience shows that smooth liners are best. Rough-surfaced liners can be run at lower speed, to produce a given amount of tumbling, and, although for a given speed they require more power than smooth liners, yet the power consumed for a given amount of tumbling is less.

Size of balls should be proportioned to the work to be done, *i.e.*, the size of particle that must be broken and the size of product desired. Large and hard particles are best broken by impact, hence coarse feeds and hard ores require larger balls than finer feeds and softer ore. But impact is a function both of the weight of the falling body and the distance through which it falls, so with mills of large diameter or with high mill speeds and consequent free parabolic fall, balls need not be as large as with the reverse conditions. The usual maximum size is 5-in., but 6- and even 7-in. balls have been used in a few places.

At ALASKA-JUNEAU 5-in. balls failed to crush the ore, but 7-in. balls succeeded (*120 P 17*). At CATEMU (*123 P 886*) a 4½-ft. × 16-in. conical mill was used to crush −1.5-in. feed (see Table 11). Increase in size of balls from 4-in. maximum to 5½-in. decreased the amount of coarse material discharged but did not increase capacity to 12 per cent. +80-mesh. With feed coarser than 0.75-in. common practice is to feed nothing smaller than 5-in. balls, and at some plants all balls smaller than 3-in. are removed from the mill periodically. At SHATTUCK ARIZONA (*110 J 760*) balls smaller than 2-in. are removed when possible. At TIMBER BUTTE all balls smaller than 3-in. are sorted out.

Balls smaller than 1-in. tend to discharge automatically from non-grate mills when the pulp is thick and the ball load is kept well up to the center of the mill. Removal of small balls is based on the reasoning that a large particle is just as likely to be struck by a small ball as by a large, and that if the small ball is unable to crush it the blow is wasted, hence there should be no ball present that is incapable of crushing the largest particle in the feed. With feeds finer than 0.75-in. the maximum size of ball may be less than in the above instances. Davis (*61 A 255*) tested for the proper size of ball for −0.25-in. feed. His tests (see Table 31) indicate that on such feed a mixture of 2⅜- and 2-in. balls is superior to a mixture of 5-, 4-, 3- and 2½-in. balls both in tons of −200-mesh material produced per 24 hr. and per hp.-hr. The test also indicates that heaping up of one or two sizes in the classifier sands, such as at 48- and 100-mesh in the test with large balls, signifies improper operation from one cause or another, while more regular size distribution of the sands signifies proper operation. This conclusion is confirmed by the tests presented in Table 36 from which Davis draws the further conclusions that if heaping occurs in the coarser sizes the balls are too small or the mill speed too low, or both, while if heaping occurs in the finer sizes the balls are too large or mill speed too high, or both. The effect of small change in ball size is clearly shown in comparing tests 8 and 9 of Table 36. The average size of ball in test 8 was 2¼-in.

Reasoning along the line that the amount of crushing done is in proportion to the number of crushing blows struck, then the smaller the balls the more the crushing, provided each ball is large enough to strike a crushing blow. From another viewpoint, if the amount of crushing done is proportional to the effective crushing surface, then the smaller the balls the greater the surface for a given weight of charge, provided again that the balls are heavy enough to provide effective crushing surface. This conclusion seems to be borne out in practice.

Table 31. Comparison of performance of large and small balls in 8-ft. × 22-in. conical mill. (*After Davis*)

	Large balls	Small balls

Delano and Rabling (*66 A 106*), crushing −9+2-mm. feed through 10-mesh in a conical ball mill, found highest capacity and lowest slime production with the largest proportion of 5-in. balls in the mill. At Miami Copper Co. in 8-ft. × 22-in. conical mills with 14,000- to 15,000-lb. load, taking a feed containing 2 per cent. on 3-mesh, a ball charge consisting originally of 4000 lb. of 4-in. and 10,000 lb. of 2-in. balls, with 4-in. balls fed daily, discharged a product containing 24 per cent. more +48-mesh material than the discharge from a parallel mill with 2-in. ball charge, but otherwise operating identically.

Table 32. Sizing test of ball charge in 8-ft. × 22-in. conical mill at Miami. (*After Davis*)

0.8 to 0.6	3.4
0.6 to 0.4	1.9
Below 0.4	0.9

Actual size of balls in an operating mill is, of course, quite different from the original charge and from the daily addition.

Table 32 shows the size distribution in the charge from an 8-ft. × 22-in. conical mill at Miami originally charged with 14,800 lb. of 2-in. balls and kept up by the addition of 400 lb. of 2-in. balls daily. Table 33 shows the charge in a 6 × 6-ft. dry-crushing cylindrical mill at Golden Cycle after 694 hr. operation with a charge of about 6500 lb. of balls, originally 5½-in., with daily addition of 5½-in. balls and periodic removal of all less than 3-in.

Shape of grinding medium. Most operators have noticed the flattened shapes assumed by the worn balls in a ball mill, and, reasoning therefrom that the greater efficiency of an established mill as compared to one newly started is due to the non-spherical shape of the old balls, have advocated the

use of such shapes as cones, single and base-to-base; cubes, disks, short cylinders, dished balls, etc. The intent in every case is to increase the area of contact between the crushing media and thereby increase, particularly, abrasion. Detailed experimental data are lacking.

Police (*116 J 553*) says that double pyramids proved best in cylindrical mills, that cubes were highly efficient for very hard and abrasive material, that single cones were better than spheres for conical mills, and that, in a rod mill, short rods were better than long. Feust (*116 J 553*) recommends disks. Hardinge (*116 J 641*) has experimented with the disk in sliming. Cubes have been tried at several plants (Chino, Nacozari, and others) but results have not been published. MacDonald (*118 J 446*) infers that results with cubes have been superior to those with rods in grinding to 48-mesh. Failing definite experimental evidence to the contrary, the moving pictures of Haultain and Dyer (*25 CMI 651*) would seem to point directly to the conclusion that balls or short cylinders, which in the rising mass of the load most readily assume rotary movement around their own axes are, therefore, most active within the load and the most efficient shapes for fine feeds. The conical and cubical shapes should be carried higher in the mill at a given speed and, therefore, cause more active cascading and more free parabolic fall and so might do more impact crushing than the sphere, which would be an advantage with coarser feeds. Scobey (*110 J 11*) tells of the trial of mill scrap, such as 6-in. lengths of 4-in. shafting, necks of stamp shoes, etc., as substitutes for balls in a 6-ft. conical mill running in parallel with gravity stamps. Capacity fell off badly. Helipebs, made of heavy steel wire coiled in the form of a helix 1¼ in. long and ¾ in. external diameter and afterward hardened, have been used in English cement plants as a substitute for balls and pebbles. Weight is 1.25 oz. each (*109 J 202*). They give large crushing surface for little weight, but in the absence of conclusive data showing efficient performance are not to be recommended.

Table 33. Sizing test of ball charge in 6 × 6-ft. cylindrical ball mill at Golden Cycle, dry-crushing. (*After Davis*)

3.5 to 3.3	5.2
3.3 to 3.1	4.5
3.1 to 2.9	4.2

Weight of charge. The usual weight is such that the struck volume of the load is between 30 and 50 per cent. of the mill volume.

Davis (*61 A 284*) recommends a load between 25 and 50 per cent. of the mill volume, stating that with a load of more than 60 per cent., interference in the falling zone is excessive, while with a load of less than 20 per cent., slip is excessive. Hines (*59 A 249*) says that maximum crushing per unit of power is attained with ball loads of about 33 per cent. of mill volume. At Miami Copper Co. when the change was made from pebble to ball charges the power installed was insufficient to run the 8-ft. × 22-in. conical mills with full ball load (30,000 lb.) and but 15,000 lb. were charged. In tests against a 6½-ft. (inside) by 42-in. conical mill (made by lagging an 8-ft. × 22-in. mill), charged with 26,000-lb. balls, the smaller mill did slightly better work in open circuit but not such good work in closed circuit. Comparative efficiencies (Stadler method) were 100 and 92. Liner consumption was much less in the small mill but ball consumption was about the same in both. At Asturiana de Minas (*115 J 395*) comparative tests were run with charges of different weights (see Table 34). The product of the lighter charge contained 17 per cent. +40-mesh against 14 per cent. from the heavier charge, but fine material was produced at a much higher rate per unit of power with the lighter charge. Table 35, showing the effect of smaller percentage variations in weight of load, shows lower ball consumption with the smaller ball load, but while the trend of the grinding data is the same as at Asturiana, the details are not wholly consistent. *Truscott's* recommendation that the load for coarse feed should be less than that for fine is out of line with these results. Young's experiments (*58 A 126*) indicate that increase in ball load causes a decrease in the power consumed per ton of load (see Fig. 16) and a finer product, from which facts the conclusion is that the maximum load that a mill will carry is best. It is to be noted, however, that at Catemu (*123 P 888*) it was found impossible to introduce feed into a 5 × 4-ft. grate mill with ball-load up to the axis.

Table 34. Effect of weight of ball charge on product of a 4.9-ft. (diameter) conical ball mill. (*After Barcena y Diaz*)

a Feed −2-in. *b* Average feed rate, 60 tons per 24 hr.

Speed depends primarily upon the size of feed and diameter of mill. Movement of balls in a properly operated mill is indicated by the moving pictures of Haultain and Dyer (*25 CMI 651*) to consist of two distinct varieties of motion: (1) rotation around their own axes parallel to the mill axis, (2) cascading or free-falling. Fig. 17 represents the action in a mill operating at proper speed for crushing coarse feed. In the lower part of the mill balls are in layers concentric with the mill shell. The layer in contact with the shell itself is moving at substantially the same rate as the shell; the rougher the mill lining the less the slip. Any ball in this layer, between lines *a–a* and *b–b*, is subject to two sets of forces, one applied at the point of contact with

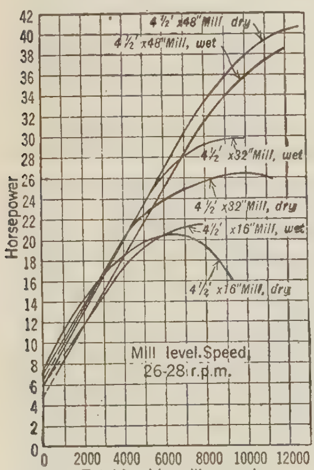

FIG. 16.—Variation in horsepower with weight of ball load. Conical mill, 4½-ft. × 16-in.

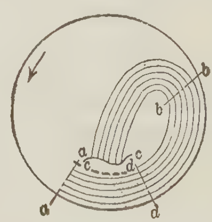

FIG. 17.—Diagram of ball action in a properly-operated coarse-crushing ball mill (*after Haultain and Dyer*).

Tests 7–9 inclusive were run at higher feed rates (300 tons per 24 hr.) than tests 1–6 inclusive. In test 7 the circulating load became so large that the test had to be discontinued.

the mill shell, in a direction tangent to the shell and (in Fig. 17) counterclockwise, the other applied on the opposite side of the ball and oppositely directed. This pair of forces acting on any one ball constitutes a couple and, since the ball is constrained by contact with the shell and with its neighbors, it rotates around an axis perpendicular to the plane of the couple, *i.e.*, parallel to the mill axis. The balls in the adjacent layer are similarly acted upon and similarly rotate and every ball in the zone between *a–a* and *b–b* has similar rotation under the action of similar couples. This motion of individual balls is shown in Fig. 18. The result is grinding by abrasion. In the zone from *b–b* to *a–a*, reckoning counterclockwise, in a mill properly operating on coarse feed, there is substantial free fall of balls out of contact with each other and no grinding or breaking action whatever. At the surface *c–c* there is crushing by impact between the falling balls and the balls below this surface, which are supported by the mill shell. In the zone *a–a*, *c–c*, *d–d*, there is most intense and turbulent motion, appearing, in the moving pictures, to consist of violent tumbling in the region above the heavy dotted line and rapid shear of the mass along the dotted line with the portion of the balls below the line moving rapidly with the mill shell and those above appearing, as a mass, to be stationary, although each individual in this mass is in rapid movement with respect to its neighbors. Haultain and Dyer describe the zone *a–a*, *c–c*, *d–d* as the "TOE"; it is apparently the most active region in the mill and the place where the most grinding is done.

FIG. 18.—Action of crushing bodies in the layers adjacent to the shell of a cylinder mill.

Hines (*59 A 249*) takes the view that substantially all the crushing is done by impact, that abrasion is unimportant, and that there is substantially no rotation of the balls, but the moving pictures are practically conclusive on this point, and the effectiveness of fine-grinding mills at speeds far below those necessary for parabolic fall points to abrasion as a dominant factor in fine crushing.

If a mill is operated at a sufficiently high speed, all of the balls will cling in concentric layers within the shell and there will, of course, be no crushing. The speed at which cling of the outer layer just occurs is given by Davis (*61 A 266*) as $N = 54.19/\sqrt{r}$, where N = r.p.m. and r = the radius inside the shell in feet. Usual speeds in the mills range from 60 to 80 per cent. of this figure.

Davis (*61 A 257*) shows that the speed of a mill is closely related to the size of balls and that proper correlation is indicated by the sizing test of the return sands from the mill classifier. His tests are summarized in Table 36. With any given size of ball, increase in speed results in decrease of coarse material in the classifier sands, *i.e.*, in increased crushing of the coarser part of the mill feed. This fact appears in each of the three series of tests summarized (1 to 3 incl.; 4 to 6 incl.; and 7 to 8), but it is most striking in the third series. According to Davis, if speed is too low, the ball size being right for the feed, there is heaping up of material in the coarser sizes of classifier sand; if too high, heaping up in the finer sizes.

Haultain and Dyer (*25 CMI 651*) show that the fine material in the pulp in the mill segregates against the shell at high mill speeds and at the inactive spot near the center of the load at low speeds. The speed of best dispersion is considerably below that of parabolic fall of balls. For fine grinding the best speed will be that at which dispersion is best.

Reduction in speed is one of the most important advances in ball-mill practice. Originally 8-ft. mills were run at 22 to 26 r.p.m. Reduction to 15 or 16 r.p.m. resulted in decreasing power consumption by 25 to 33 per cent., substantially halving ball wear, and markedly decreasing liner wear, without changing capacity to any appreciable extent.

Pennick (*120 P 459*) recommends that the speed be made dependent on the size of product desired and suggests 375 to 400 ft. per min. peripheral speed (in an 8-ft. mill) for 48-mesh product and 550 to 625 ft. per min. for 8-mesh product. Wiggin (*59 A 245*) says that reducing the speed of the 7½-ft. × 72-in. conical mill at Anaconda from 23 to 15 r.p.m. reduced power consumption from 215 to 140 hp. and ball consumption from 4.5 to 3.25 lb. per ton crushed, while feed rate and size of product were substantially unchanged. A similar result is reported at Asturiana de Minas (*115 J 395*). A 4.9-ft. conical mill drew 40 hp. at 34 r.p.m. and 32 hp. at 30 r.p.m. Decrease in speed produced no appreciable difference in product with the mill crushing 60 tons per 24 hr. of −2-in. feed. See also Table 11, Anaconda, 7½-ft. × 72-in. and Consol. Ariz. Smelting Co., 8-ft. × 36-in. mills. Dowsett (*108 J 185*) says that at Bluestone Mining and Smelting Co., where it was possible, by means of a water rheostat to control mill speed very closely, variations of as little as ½ to ¼ r.p.m. made marked difference in capacity. At Miami results in closed-circuit grinding in underloaded 8-ft. × 22-in. conical mills was slightly improved by decreasing the speed and increasing the ball load from 15,000 lb. to an amount that held the power at the same figure as with the higher speed and lighter load. At American Graphite Co. (*120 P 569*) lack of crushing in a 6-ft. × 22-in. conical mill, due to the lubricating character of the feed, was remedied by increasing the speed. At Nevada Cons. Cop. Co. an 8-ft. × 30-in. conical ball mill with 30,000-lb. ball charge drew 130-hp. at 28 r.p.m. and made a product containing 8 per cent. on 48-mesh; at 21½ r.p.m. it ground 451 tons of −6-mesh feed per 24 hr. to 19.8 per cent. +48-mesh with an expenditure of 115.1 hp.; the same size mill at 17 r.p.m. ground 494 tons per 24 hr. from 18.6 per cent. + 1-in. to 5.2 per cent. +48-mesh, with the consumption of 109 hp. and at a cost of $0.059 per ton.

Shape of mill. The diameter of a ball mill is principally determined by the size of the largest particles to be crushed, while the length is, to a considerable extent, dependent upon the size of product desired. Diameter of mill, size of balls and speed together determine the force of the crushing blows. With balls of the usual size (5-in. maximum) a mill run at a speed to permit some free parabolic fall should be at least 3 ft. diameter for particles up to 0.5-in. in size, 5 to 6 ft. diameter for particles of 1-in. size and 8 ft. for 2- to 4-in. particles. The amount of coarse oversize in the discharge will be materially lessened if a mill of more than the minimum diameters given is used for any given size of material. Increase in length increases the amount of fine material produced in a single pass, but since power consumption also increases with increased length the amount of such material produced per horsepower-hour does not necessarily increase.

Table 37 shows the results of a test on a 4½-ft. mill with three different lengths of cylindrical section. With the feed rate constant, the tonnage of −200-mesh material produced per hp.-hr. shows a maximum with 32-in. cylinder, while the amount of −65-mesh per hp.-hr. is a maximum at 16-in. Tables 84 and 86, showing the performance of 8-ft. × 22-in. and 8-ft. × 66-in. conical ball mills at Miami Copper Co., indicate that the shorter mill is the more efficient in producing both −48-mesh and −100-mesh material. It is to be noted, however, that the longer mill was in re-grinding service, with the harder feed, and that it was making the finer product. These tests and practical experience both show that the finer the product desired the longer the mill necessary and that an excessive increase in mill length reduces mill efficiency.

The usual ratio of diameter to length in modern cylindrical mills ranges from 1 to 1.6, the greater ratio corresponding to the coarser product. Conical mills have a ratio of diameter to length of cylindrical section varying usually between the limits of 2.5 and 4.3. In closed-circuit grinding a small deficiency in either length or diameter can be overcome by increase in the amount of circulating load. For this reason mills of smaller diameter

than otherwise can be used for coarse feed and mills of smaller length than otherwise to produce fine products. But this does not alter the fact that wrong proportions will not give the most economical operation.

Table 37. Effect of length of cylindrical section on performance of conical ball mill (58 A 126)

Length of cylindrical section, inches	Ball charge, pounds	Horsepower	Product			
			−200-mesh		−65-mesh	
			Per cent. weight	Tons produced per horsepower-hour	Per cent. weight	Tons produced per horsepower-hour

Mill, $4\frac{1}{2}$-ft. nominal diameter. Moisture, @ 40 per cent.; feed rate, 18 tons per 24 hr.

Slope. In the early days of ball-milling the mills, particularly conical mills, were set with the axis slightly sloping toward the discharge end. The purpose served was to produce a more granular product than could be made with the axis horizontal, all other conditions being the same.

Table 38 presents the results of a test with three different slopes. It would appear to show the most granular product at the intermediate slope, but the moisture content of the pulp in this test was considerably lower than in the last test and since other tests in the series indicated that fineness of product increased with increase in pulp moisture (see Table 29), it is probable that higher moisture would have placed the second test intermediate in results between the two others.

Table 38. Effect of slope on performance of $4\frac{1}{2}$-ft. × 16-in. conical ball mill (a)

Slope, in. in mill length	0	1.25	2.62
Moisture, per cent.	36.5	31.7	38.5
Weight of ball load, lb. (5, 4 and 3-in.)	4264	3550	2819
Horsepower	20.1	20.1	17.7
Coarsest product	0.2 per cent. on 6.68-mm.	0.2 per cent. on 6.68-mm.	0.1 per cent. on 9.42-mm.
Per cent. −65-mesh in product	55.2	46.7	48.9
Per cent. −200-mesh in product	24.4	19.5	21.6
Average size of product, mm.	0.246	0.316	0.288

a Feed, 18 tons per 24 hr., 0.7 per cent. on 1.5-in.

Mills are rarely sloped in present-day practice, due to the fact that the same result can ordinarily be obtained by regulation of the classifier and the feed rate and that sloping causes undue thrust on trunnion bearings, difficulty in countershaft alignment, and excessive wear of gears.

Grate opening may be made to control capacity and the amount of oversize in the mill product. Fig. 19 (59 A 2.?) shows the result of change in this factor on tonnage and size of product when all other conditions of operation were kept constant. It is better, however, to use a grate with large

openings and depend on outside control of product size. This is especially true when the changed result desired is one that would call for a smaller grate opening. The grate is not intended to be a sizing device and should not be used for one.

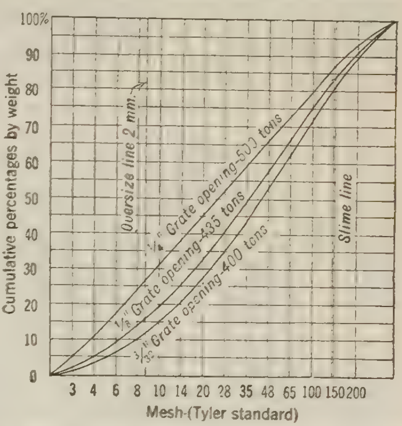

Fig. 19.—Effect of grate opening on ball-mill operation.

Power consumption. (See also Art. 6.) Figures from practice are given in Tables 4, 5 and 11. Power consumption increases with increase in ball load until the load reaches a point at or slightly above the axis, after which further loading may result in decrease of power (see Fig. 16).

At the Quincy mill an 8-ft. × 36-in. conical mill taking 350 tons of feed per 24 hr. in open circuit consumed 128 hp. at 28 r.p.m. with 20,000 lb. of balls (actually 1¼-in. drill-steel scrap in 4- to 6-in. lengths) or 12.8 hp. per ton. With 31,000 lb. of balls, power consumption was 12.4 hp. per ton, and with 32,000 lb. 12.1 hp. per ton. At 18 r.p.m. and 20,000 lb. of balls, consumption was 8 hp. per ton and at 20 r.p.m. and 32,000 lb. of balls, 7.6 hp. per ton.

Power consumption is higher with thin pulp than with thick because of segregation of balls near the periphery of the mill and consequent displacement of the center of gravity of the total load toward the periphery.

Power consumption increases with increase in speed within operating limits. (See "Speed" p. 402.)

Power with rough liners is more than with smooth, is greater per pound of ball load with large mills than with small, and is greater with balls of mixed sizes than with balls of one size only.

Power consumed per ton of ball load is somewhat different with different types of mills. The range with conical mills is from 6.2 hp. per ton of load to 15, average 10.2 hp. With simple trunnion mills the corresponding figures are 11.2, 18.9 and 14.1 hp. (excluding two mills whose length is twice the diameter, or more). With grate mills the figures are 7.2, 21.8 and 13.8 hp.

Much of the power consumed in ball milling is transformed into heat and becomes apparent in rise of temperature of the pulp in passing through the mill. (See Table 39.)

Table 39. Pulp temperatures in ball mills at Nevada Consolidated Copper Co.

Mill number	Temperature of feed, degrees C.	Temperature of discharge, degrees C.	Increase, degrees C.
1	25	35.5	10.5
2	25	40	15
3	26	39	13
4	26	39	13
5	26	37	11
6	27	49	22
7	22	43	21
8	21	40	19
9	18	40	22
Average	24	40.3	16.3

The amount of temperature rise is proportional to the percentage of solids in the pulp. Occasionally, in the Nevada Consolidated mills, when the percentage of solids rises to between 75 and 80, the temperature rises to 50° C.

Selection of a ball mill. Hines (*59 A 249*) suggests an ingenious method for choosing a ball mill for a given service. After making a reliable determination (or the best possible estimate) of the tons per horsepower-hour to be expected in grinding from the given feed size to the desired size of product, divide this figure into the hourly tonnage to get the power requirement, then choose a mill of such size that, with the proper volume of balls, the power rating will correspond.

Example. Desired a ball mill to grind from 2-in. to 8-mesh. at the rate of 5 tons per hr. From p. 396 the average "Tons per hp.-hr." grinding from 2- or 3-in. to 6- or 8-mesh is 0.200. The power required is therefore $5/0.200 = 25$ hp. This corresponds to a load of 3600 lb. of balls in a grate mill or 4900 lb. in a conical mill. The corresponding mill sizes (Tables 10 and 11) are a 5-ft. × 22-in. conical and 4 × 5-ft. or 5 × 4-ft. grate mill. With coarse feed the mills of larger diameter are the better. According to Tables 16 and 17, either of the 5-ft. mills would do the work, if the rock was not exceptionally hard and tough.

Another method of attack is to take the weight of charge in the mill at, say, 300 lb. per cu. ft. and ball charge as occupying, say, 40 per cent. of mill volume inside of grates and liners. Then the desired mill volume is $3600/30(0.40) = 30$ cu. ft. Since at least a 5-ft. mill is needed for 2-in. feed, the cross-sectional area inside the liners will be about 15 sq. ft. and the least required length 2 ft. The 5 × 4-ft. mill has somewhat in excess of the required volume, inside grates and liners. Care should be taken not to choose a mill too large for the duty required, since such a mill over-grinds, wastes power, and steel consumption is excessive. If, however, this condition must be met, power and steel consumption can be reduced by reducing speed and ball load.

Operating ball mills. Tonnage, size of feed, moisture content, and ball load must be kept as nearly constant as possible, if maximum efficiency of operation is to be attained. A moisture flask (see Sec. 22, Art. 23) and an ammeter on the driving motor are useful aids. The ammeter will indicate relatively small changes in tonnage or ball load and is sensitive also to somewhat larger changes in moisture content. If the ball load is below the mill axis, a drop in the ammeter reading means decrease in ball load, increase in feed tonnage or decrease in moisture. In starting a new mill, run empty for some time to make sure that all is right mechanically, then stop and charge in the grinding media with plenty of ore, preferably fine, to act as a cushion and prevent excessive hammering of the lining when the mill starts. Hammering will start leaks in the liner bolts and with cast balls or lining may cause breakage.

The following difficulties encountered in operation at ALASKA-JUNEAU (*122 P 633*) were all due to structural defects, which should be guarded against in designing. The feed trunnions were too long and the diameter too small for coarse feed. The feed scoop was too small. The discharge bell had too little flare so that grit worked back into the discharge-end bearing. The clutch pulley on the pinion shaft slipped and had to be replaced by a keyed pulley with belts and motor sufficiently large to start the load. The floor space allowed was too small for convenient repairing. The crane carriage did not extend over the feed end, hence scoop changes had to be made with hand tackle. Other frequent faults of construction that cause operating difficulties are: Lack of sufficient slope in feed and discharge launders (see Sec. 20, Art. 10) and failure to provide convenient methods for handling dumped loads, whether from mill or classifier, back into the circuit.

Arrangement of ball mill and mechanical classifier in closed circuit. The important points to be observed are launder slopes, protection of motors and gears against splash, adequate protection of operators, particularly from feed scoop and gears, and clearance around the mill for handling liners.

When open-trunnion mills are operating in closed circuit with a classifier, provision should be made to divert wood chips and worn balls from the classifier. This may be done by placing a flat stationary screen over the mill-discharge box (in which case the screen must be cleaned periodically by an attendant) or a revolving screen may be placed on the end of the discharge spout.

Cost of ball milling. At McIntyre-Porcupine the average for the 15 months ending June 30, 1917, was \$0.1469 per ton, made up: labor \$0.0228, supplies \$0.0763, power \$0.0414, shop \$0.0064. *(Official report.)* Poirier *(51 A 128)* says, in the light of experience at Vipond-Porcupine, that attendance and maintenance of a conical ball mill taking −2-in. feed and grinding to 8-mesh should not exceed \$0.10 per ton (1914). At Elko Prince the average cost over the three years ending 1918 on a 43½ Marcy mill (see Table 5) was \$0.246, as follows: repairs, \$0.0253; labor, \$0.0154; liners, \$0.1042; balls, \$0.1011. Costs at United Eastern *(63 A 553)* in 1917 and 1918 are given in Table 40.

Table 40. Costs of ball milling at United Eastern, 1917 and 1918. *(After North)*

9. Ball mills *vs.* other intermediate and fine grinders

General. The principal competitors of the ball mill are rolls, disk crushers and gravity stamps in the range from 3- or 4-in. to 0.5-in., rod mills throughout the ball-mill range, and pebble mills in the range from 0.25-in. to slimes. Roller mills and grinding pans, while cheaper in first cost, are not real competitors, on account of low capacity and high attendance and maintenance charges.

Ball mills *vs.* rolls or disk crushers. This battle has not yet been fought out to the entire satisfaction of mill men generally. The performances at Miami, Inspiration, Engels, and Consolidated Arizona Smelting Co., cited on p. 395, surely favor the Miami practice and indicate that rolls (or disk crushers) are cheaper than ball mills in crushing from 2- or 4-in. to 0.5- or 0.75-in., and should be installed for this service, notwithstanding the greater complexity of the flow-sheet, when the capacity of the plant is sufficient to keep both machines busy.

Ball mills *vs.* gravity stamps. It is not to be concluded from the preponderance of stamps in gold mills that it is the world-wide judgment of mill men that the stamp is superior to the ball mill in gold milling. Most of the world's big gold mills date back beyond the modern development of the ball mill and were equipped with stamps before the ball mill was seriously considered as a competitor. Since stamps are expensive and long-lived machines, their rejection from an operating mill is to be considered only on a clear showing of enormous superiority by the competing machine and then would be justified only in large plants. For new plants the comparative advantages and disadvantages of the two machines are as follows: (1) The gravity stamp has a smaller unit capacity and the efficient, large-sized units can be used for small mill tonnages. A heavy (1750- to 2000-lb.) gravity stamp can crush −4-in. feed to pass a 0.5-in. or 0.38-in. screen at the rate of, say, 15 tons per stamp per 24 hr. and one stamp (Nissen) can be installed as an efficient unit. A ball mill 8 ft. diameter with a daily capacity of, say, 1000 tons per 24 hr. is required for the same service. Furthermore, the stamp can be made to grind down to a size suitable for cyaniding many ores (65-mesh) at the rate of 4 to 6 tons per stamp per 24 hr. or, say, 0.05 ton per hp.-hr. while the ball mill will not grind at this rate of power consumption, if crushing less than 250 tons per day. Hence for small tonnages of coarse, hard feed the stamp

has undoubted superiority. (2) When large capacities are to be handled from crusher product (2- to 4-in.) to cyanide size (say, 1 to 10 per cent. on 100-mesh), and both machines are used as intermediate crushers only, 2-stage crushing with a pebble mill the second stage in both cases is the basis of comparison.

At San Rafael mill, Pachuca, Hidalgo, Mex., a 20 @ 1250-lb. stamp battery fitted with 0.27-in. screen was run for three months against a 6 × 5-ft. grate mill. Screen tests of the common feed and both products are given in Table 41. Both machines were run at their normal rates. For the ball mill this was 250 short tons per day, open circuit. Relative costs are given in Table 42. Since the products were so nearly of the same size, the costs of pebble milling were the same in both cases At the Socorro Mining and Milling Co., Mogollon, N. M., stamps and conical ball mills came into competition in grinding a mixture of andesite, rhyolite, trachyte and quartz. Comparative data are given in Table 43.

Wile (*99 J 693*) in a comparison based on the performances of an 8 × 5-ft. Marcy mill at Utah Copper Co. and gravity stamps at Treadwell, concludes that relative average costs of ball-milling and stamping, for breaking from − 1.5-in. to tube-mill feed are $0.08 and $0.13 per ton respectively. He takes repairs to be the same (4¢ per ton) but makes 2.5¢ per ton difference in favor of the ball mill on both power and labor items. These comparative costs are of the same order of difference as those at San Rafael (Table 42) but it is probable that the cost of repairs (including steel renewal) is higher with a ball mill than with stamps notwithstanding the greater complexity of the latter and the more frequent breakage of parts, and that the correctness of Wile's conclusions follows because the discrepancies in power and labor requirements are greater than he allowed for. Morse's summary (*113 P 938*) is rather generally supported by the facts in the case of large installations. He says that the ball mill is cheaper in first cost, cheaper to set up, requires less floor space and head room, consumes less power, is simpler to operate and maintain, and is more flexible in performance when run in closed circuit. Its only disadvantage is the higher steel consumption.

Ball mills *vs.* rod mills. See Art. 12.
Ball mills *vs.* pebble mills. See Art. 16.

10. Screen-discharge ball mills

Krupp ball mill, is shown in Fig. 20. The inner shell containing the grinding media is built up of hard-iron or alloy-steel wearing plates (*a*), containing coarse perforations as shown. These plates are bolted between heavy cast heads which are, in turn, fastened to a heavy through shaft. One end of the shaft carries a large gear, driven by means of the pinion and pulley shown. Surrounding the perforated plates (*a*), are circumferential sections of punched-plate screen (*b*) with relatively coarse aperture, and surrounding this a ring of fine screens (*c*). Both sets of screens are bolted to the heads and revolve with them. The revolving part is all contained in a sheet-iron housing (*d*), having a hopper bottom for discharge of screened material. In operation feed is introduced at one end of the cylinder at the center around the shaft. When sufficiently ground by the balls to pass the large apertures in the grinding plates (*a*), the material passes through to screen (*b*). That part of the ground material that will pass the relatively coarse meshes in screen (*b*) does so, and is subjected to screening by the fine screens (*c*). The material that passes through these fine screens discharges from the hopper finished. That material that will not pass through screen (*c*) is carried around in the space between (*b*) and (*c*) to the position marked (*e*), when it falls through opening (*f*) into chamber (*g*) and joins material that passed the heavy liner plates but would not pass screen (*b*). From chamber (*g*) both materials pass through an opening at (*h*) back into the crushing chamber and are there again subjected to crushing action by the balls. Table 44 gives data on commercial sizes of this

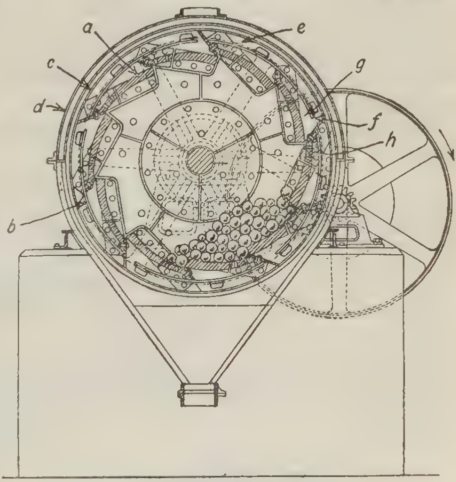

Fig. 20.—Krupp ball mill.

machine as furnished by one manufacturer. The balls used are the same as those used in other ball mills.

Table 44. Sizes and weights of Krupp ball mills. (*Catalog data*)

Size numbers	Weight without charge, pounds	Weight of balls, pounds	Capacity on Portland cement clinker to 20-mesh	Horsepower required
7	29,500	3000	12 to 16 bbl. per hour	30 to 40
8	41,100	4500	18 to 24 bbl. per hour	40 to 50

From 100 to 120 per cent. additional power is required momentarily in starting. When pulverizing to pass 20-mesh, from 30 to 40 per cent. will pass a 100-mesh sieve.

These mills are made for either dry or wet crushing. In the latter case the bottom of the housing is a spitzkasten in which water stands at such a level that the fine screen dips into it at the lower part of its revolution and is washed. The lifters that return oversize of the fine screen also serve as water lifters and thus introduce water into the grinding zone.

A special field for these mills has arisen in sampling plants handling materials containing a large percentage of metallics. With such material this mill is peculiarly suitable, in that it will discharge the metallics that are sufficiently fine to be susceptible to ordinary sampling methods, but retains those particles that are too coarse and collects them so that they are available for melting and sampling by bullion methods.

Wet mills have been very little used because of high metal and screen consumption.

Allen (*114 P 362*) tells of a 5-ft. mill wet-crushing − 1.5-in. feed through 20-mesh at the rate of 60 tons per 24 hr. and drawing 20 hp. The rock was exceptionally hard. As compared with dry crushing the greater capacity with no increase in power consumption more than compensated for the greater metal consumption.

The dry mill has been rather extensively used in industrial grinding, particularly in cement plants. Its use in metallurgical work has been restricted to plants that crush dry for roasting.

At Mt. Morgan (*102 J 755*), No. 5 mills were used to crush dry from − 2-in. through 50-mesh screens. The product contained 10 to 15 per cent. + 60-mesh. Charge, 2000 lb. of 6-in. balls; speed, 20 r.p.m.; 15 hp.; capacity, 22 to 24 tons per 24 hr. James (*111 J 199*) reviews West Australian practice and states that at South Kalgoorlie No. 5 mills crushed from − 2.5-in. through 30- to 40-mesh screens at the rate of 100 tons per 24 hr. with a ball consumption of 0.5 lb. per ton. Liners lasted 8 months. Screening ahead of the mills increased mill capacity markedly as it prevented overloading the mill screens. With 20-mesh screens, sizing analysis of product with this friable ore was as shown in Table 45 (*83 J 475*). At the Perseverance mill, Kalgoorlie (*16 MM 204*), No. 8 mills (about 9 ft. diam. by 4 ft. long) with 4400 lb. @ 4½-in. forged-steel balls ground 100 tons per 24 hr. from − 1.5-in. through 28-mesh, dry. Speed, 24 r.p.m.; power draft, 55 to 60 hp. Ball consumption, including − 2-in. balls rejected, was 0.5 lb. per ton milled and life of manganese-steel liners was 6 to 9 months.

Krupp ball mills *vs.* **rolls.** At a Bolivian silver-tin mine (*64 A 676*) the crushing problem was dry grinding from 2-in. maximum to approximately 10-mesh for roasting. The original installation was a No. 4 Krupp ball mill which, fitted with 1.2-mm. screen, ground to the

size shown in Table 46. This was displaced by two 36 × 12-in. rolls in series, the first in closed circuit with a 3/8-in. trommel, the second with a No. 8 Newaygo screen with 0.078-in. opening. The sizing test of the product is given in Table 46. Roll crushing was at the rate of 0.085 ton per hp.-hr. with a steel consumption of 0.38 lb. per ton of finished product. The cost of the roll product was less than one-third that of the ball-mill product.

Table 46. Comparative performances of Krupp ball mills and rolls at a Bolivian mill. (*After Söhnlein.*)

150	3.5	4.5
−150	32.0	22.0

Ferraris mill (Fig. 21) is a grate mill with a screen (*a*) forming an extension of the mill shell at the discharge end. The screening compartment has a conical imperforate inner surface (*b*) and closed end (*c*) and is compartmented by means of radial partitions. Material flows through grate (*d*) into the screen compartment at the lower part of the mill, is elevated and screened therein and oversize passes back into the mill when the compartment reaches top position. The mill is made in 5- and 6-ft. diameters. The smaller mill is rated to crush 50 tons per day through 10-mesh or 25 tons through 30-mesh from −2-in. feed and the larger mill double these figures. The mill has been very little used and is principally interesting as foreshadowing the present-day grate mill.

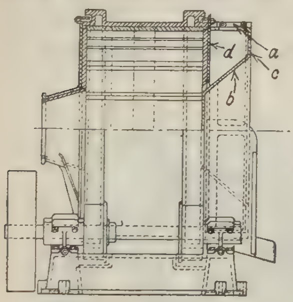

Fig. 21.—Ferraris ball mill.

Herman mill (Fig. 22) is built on the same basic principle as the Krupp mill, *i.e.*, trunnion feed and peripheral screen-controlled discharge, but is simpler in construction. The heads are joined by a heavy sectional grid with coarse openings tapering outward. Around this is fastened a heavy punched-plate screen on the outside of which is strapped the fine screen that determines discharge size. The heavy grid serves several ends. It is the structural link between the heads, it is a rough-surfaced liner, acting to a small extent like the ribbed liners of the El Oro type and protecting itself by the balls so held, and it holds back the largest of the feed particles from the punched plate.

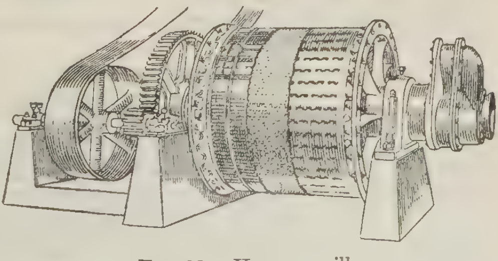

Fig. 22.—Herman mill.

Schmidt Kominuter is a peripheral screen-discharge ball mill of the usual type with screens set on a conical surface surrounding the perforated grinding cylinder. Oversize moves into a lifting compartment in the feed-end head and joins new feed. The mill may be run either wet or dry.

Performance. At Golden Cycle (*60 A 119*) the mills are fitted with diagonal-slotted screens having 3.6 × 12.7-mm. openings. Screen tests of products (dry-crushing) with new and with worn screens are given in Table 47. The effect of difference in screen size is shown principally in the coarser sizes. Wear of manganese-steel balls was 0.7 lb. per ton (*113 P 938*).

Table 47. Sizing test of product of Schmidt Kominuters at Golden Cycle (dry-crushing). (*After Blomfield and Trott*)

Screen aperture	Per cent. weight	
	Worn screens	New screens

200	4.2	4.4
−200-mesh	12.9	13.6

11. Rod mill

Description. The rod mill consists of a heavy steel cylinder, usually with a length between two and three times the diameter, filled with rods up to somewhat below the mill axis, and slowly revolved. The feed end of the cylinder is closed with a head provided with a central opening for introduction of feed. The discharge end is treated differently according to the type of mill. In trunnion mills it is closed by a head provided with a central opening through the trunnion for pulp discharge. In open-end mills, the discharge end is carried on rollers, and the discharge-end plate is a relatively narrow ring beveled inward at the center and loosely closed by a circular swinging door, separately supported. (See Fig. 23.) Space is left between plate and door for discharge of pulp. In this open-end mill the pulp level is considerably lower than in the trunnion-discharge mill. A quick-discharge grate mill, similar to the grate ball mill is also on the market.

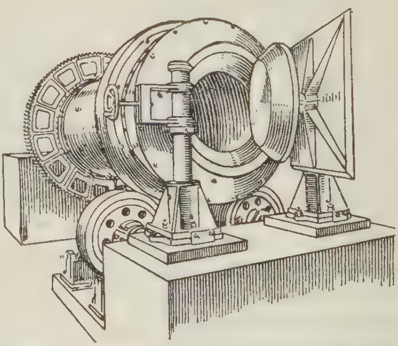

Fig. 23.—Marcy open-end rod mill, discharge end.

Shell is made of heavy steel plate with welded butt joints reinforced with heavy, double-riveted butt straps. Heavy cast flanges for attachment of heads are double-riveted to the ends of the shell, carefully faced for tongue-and-groove joint and drilled for bolts. Heads are usually cast semi-steel, machined and drilled to fit the cylinder flanges. No manholes are provided. In open-end mills, the discharge opening is large enough to permit introduction of liners and in trunnion mills the discharge head is removed for this purpose. Trunnions are cast integral with the heads and carefully turned to the mill axis. Tires and rollers are of hardened steel, and in one make the rollers are carried on ball bearings. Bearings and drive are similar to those used on ball mills. Liners are usually of the ship-lap or wave type (see Fig. 1) made of manganese steel, although cast iron and chrome steel are sometimes used. With smooth liners the load oscillates and wears out the liner in a few days (*112 J 1052*).

Rods are made of high-carbon steel, best 0.8 to 1.0 per cent. carbon and not less than 0.6 per cent., 1½- to 4-in. diameter, and from 1 to 2 in. shorter than the length of the mill inside the head liners. Mild-steel rods are unsuitable for the reason that they bend and kink after wearing down to a certain minimum diameter and snarl up the whole rod load

so that little or no crushing is done. The hardened-steel rods break up when they get to this size and are eventually discharged in small pieces without snarling. Rods used in primary mills, are 3- and 4-in. diameter, 1½- and 2-in. rods are used in secondary mills.

At Iron Cap (111 J 897) 3-in. rods are charged in the primary mill and removed at 2-in. These worn rods are then charged into the secondary mills, from which they are removed at ⅛-in. to prevent kinking.

Manufacturers' data are given in Tables 48 and 49.

Table 48. Trunnion-type rod mill. (*Allis-Chalmers catalog*)

Size of mill, diameter × length feet	Weight of average rod charge pounds	Approximate capacity in tons per 24 hr.; material, medium-hard quartz		Horse-power to run	Horse-power of motor recom-mended	Revolu-tions per minute of mill	Approximate weights complete

a Laboratory size.

Performance at various plants is given in Table 50.

Cole-Bergman mill at New Cornelia (111 J 901) 5 × 10-ft. inside, with 32,000 lb. of 2-in. and smaller rods drew 90 hp. (= 5.6 hp. per ton of rods) at 19 r.p.m. and crushed 250 tons per 24 hr. from − 1-in. to − 48-mesh (= 0.116 ton per hp.-hr.). Central discharge was found best for wet work. This mill carries 85 per cent. of the load on roller bearings at the discharge end, although it is a trunnion-type mill. The roller bearings are ball-bearing and it is claimed save 16 per cent. of power over other types of bearings. At D. W. Jones Co., Denver, Colo. (111 J 901) a 4 × 10-ft. mill with grate discharge crushed dry from − 0.75-in. to 22 per cent. +40-mesh at the rate of 125 tons per 24 hr. (0.13 ton per hp.-hr.). Rod charge was 8000 lb. and the mill drew 40 hp. (= 10 hp. per ton of balls) at 26 r.p.m.

Capacity depends upon the same factors that influence ball-mill capacity (see p. 387). The range, according to the practice cited, is from 98 tons per

NOTES TO TABLE 50

a Italic numbers refer to column numbers in Table 50*a*. ***b*** Usual rate is between 125 and 175; product becomes gradually coarser as feed rate increases. ***c*** Changing rods and liners. ***d*** Hard cast-iron liners locally cast outlast manganese steel and, therefore, cost less. ***e*** Includes 0.129 lb. consumed and 0.024 lb. discarded. ***f*** Includes 1.238 lb. consumed and 0.223 lb. discarded. ***g*** Mill stopped and charge overhauled every half month; small and bent rods removed. Constant quantity added each day to keep up load. ***h*** See column 3, Table 50*a*, for sizing tests with 205 tons per 24 hr., open circuit. ***i*** One man attends table, rolls and one rod mill. ***j*** 500 tons per 24 hr. from 0.5-in. to 14-mesh (= 0.433 tons per horsepower-hour.); 280 tons per 24 hr. from 14-mesh to 48-mesh (= 0.243 ton per horsepower-hour). ***k*** Changing rods. ***l*** Included in other work. ***m*** 3080 lb. @ 2-in., 10,920 lb. @ 1¼-in. ***n*** Trunnion type; roller type unsatisfactory on account of mechanical troubles. ***o*** Compare 7½-ft. × 72-in. conical ball mill at the same plant, Table 11. ***p*** Two of these mills in series, the first taking − ¾-in. feed in closed circuit to table size, the second re-grinding table tailing (about 200 tons) to 0.6 per cent. +48-mesh and 38.5 per cent. −200-mesh. ***q***. Primary mill, 1.46 lb. per ton; secondary, 1.65 lb. ***r*** Primary and secondary the same. Feed-head liner semi-steel, weight 900 lb., cost at plant $159; life 81 days, 0.043 lb. per ton; discharge-head liner, semi-steel, weight 2000 lb., cost $424, 113 days, 0.097 lb. per ton; shell liner, cast steel, weight 15,000 lb., cost $2028, life 113 days, 0.52 lb. per ton. Cost of rods and liners, $0.30 per ton out of a total cost of $0.425 per ton. ***s*** Hard quartz ore. *Mine and Smelter Supply Co.* ***t*** 5 per cent. +10-mesh, 30 per cent. −200-mesh. ***u*** End liners, 0.06 lb. per ton; shell, 0.59 lb. per ton. ***v*** Two mills in series, the second in closed circuit with a classifier. ***w*** Primary, 0.48 lb. per ton (= $0.028); secondary, 0.33 lb. per ton (= $0.0175). ***x*** Primary, 1.06 lb. per ton (= $0.0374); secondary, 1.3 lb. per ton (= $0.0455). ***y*** *111 J 899.* ***z*** With a feed containing 0.2 per cent. +2-in., 1.1 per cent. +1.5-in., 4.3 per cent. +1-in., 3.9 per cent. +0.5-in. and 24 per cent. +4-mesh, total on 4-mesh = 33.6 per cent., the average daily tonnage for a month to the same fineness was 1027, ***aa*** Gold-bearing quartz and schist of medium hardness. ***ab*** *Allis-Chalmers, Bul. 1821-A.* ***ac*** Shell liner only. ***ad*** Soft limestone and galena. ***ae*** *118 J 446.* ***af*** Speeds of 15.5 and 16.5 r.p.m. were unsatisfactory. ***ag*** Estimated, on the basis that 60 per cent. of the discharge of the primary mills (which is 50 per cent. +48-mesh, see column 7, Table 50*a*) comes back to the secondary mills as sand-table tailing. ***ah*** 12 per cent. +48-mesh, 52 per cent. −200-mesh. ***ai*** Total for both primary and secondary mills = 1.6 lb. per ton of original primary-mill feed, including 30 to 35 per cent. scrap loss. ***aj*** Total for both primary and secondary mills = 2.32 lb. per ton of original primary-mill feed, including 10 per cent. scrap loss. ***ak*** 0.9 to 1.1 per cent. carbon. ***al*** Gravity chute. ***am*** *55 A 678.* ***an*** *Private communication.* ***ao*** This is selective grinding of soft country rock. The hard quartz containing the values is mostly found in the +100-mesh sizes and the flow-sheet was changed to rod mills in open circuit followed by conical ball mills in closed circuit with Dorr bowl classifiers to take care of this material. ***ap*** Discharge-end liner, 40 days; shell and feed-end liners, 81 days. Original weight of complete set, 28,000 lb., scrap 54 per cent. ***CCI*** Chilled cast iron. ***CI*** Cast iron. ***Cr*** Chrome steel. ***DBC*** Dorr bowl classifier. ***DC*** Dorr classifier. ***G*** Grease. ***HCS*** High-carbon steel. ***Mn*** Manganese steel. ***O*** Oil.

24 hr. in a 3 × 8-ft. mill to 350 tons in a 6 × 12-ft. mill grinding from 6- or 8-mesh to 48-mesh and from 440 tons in a 3 × 7-ft. mill to 720 in a 6 × 12-ft. mill grinding from about 1-in. to 8- or 10-mesh.

Power consumption ranges from 4.9 hp. per ton of rod charge in a 4-ft. mill to 8.5 hp. in a 6-ft. mill, both types having the usual bearings. Power for the Cole-Bergman mill with discharge end supported on ball-bearing tire rollers is less. Thus tons per horsepower-hour average 0.18 when crushing from 6- or 8-mesh to rather coarse flotation feed (2 to 9.5 per cent. +48-mesh) and 0.35 when crushing from 1-in. to 6- or 10-mesh for roughing-table work. The reason for the smaller power draft of the rod mill is that more rods than balls can be loaded into a given space and hence, with a given crushing load, the center of gravity is nearer the axis of revolution.

Size of feed. The rod mill should not be fed with material coarser than 1-in., and with very hard ore the feed should be finer than this. Larger lumps cause the rods to be spread so far apart at the feed end that they fail to do efficient crushing for a considerable part of their length. When fine feed (8- or 10-mesh) is introduced with the idea of sliming, the mill comes into competition with ball-tube mills and pebble mills, and is outclassed. In grinding from 1-in. to 48-mesh the work is most efficiently done in two stages.

Thus two 6 × 12-ft. mills at Copper Queen (Table 50) crushed from 1.5-in. to 48-mesh at the rate of 0.219 ton per hp.-hr., while the 5 × 10-ft. Cole-Bergman mill at New Cornelia crushed from 1-in. to 48-mesh at the rate of only 0.116 ton per hp.-hr.

Size of product. The product of a rod mill is remarkable for its granular character and the large percentage near the limiting screen size. This is particularly true in open-circuit work or when the circuit is closed by a screen. It is noticeable, also, that the product of open-circuit work contains very little "accidental" oversize, *i.e.*, substantially unground feed particles, even when the capacity is raised considerably above normal. Fig. 24 (*57 A 360*) shows that the result of an increase in feed rate is a relatively uniform increase in size of product, with minimum increase in the coarsest sizes.

Rod-mill product is remarkably similar in size distribution to roll product as may be seen from Fig. 25. (*57 A 361*). This similarity is, of course, to be

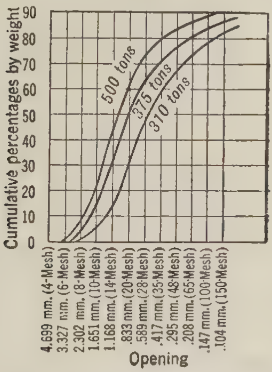

FIG. 24.—Effect of change in feed rate on product of rod mill (*after Watt*).

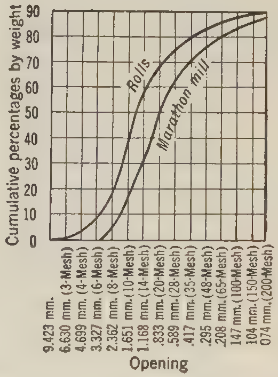

FIG. 25.—Comparison of roll and rod-mill products (*after Watt*).

expected, in the light of Haultain and Dyer's work (see p. 402), since the rods in a slow-moving mill act almost entirely like a large number of close-set rolls. Coghill and Anderson (*117 J 1006*) warn, that, under certain circumstances the rod mill may, even while making a product that is not, as a whole, unduly slimed, nevertheless slime the mineral constituents excessively, and that the usual statement that the rod mill is a granulator and not a slimer is to be accepted with caution and discrimination. Table 51, giving the results of a thorough sizing-assay test on a rod mill crushing from 0.5- or 0.75-in. feed to 20-mesh, is cited by the authors in support of this contention. Comparing the percentage of −200-mesh in the product with that in products ground to the same limiting size in ball mills (Tables 4, 5 and 11) it is apparent that the rod-mill product contains more slime and that the criticism is justified. But sliming has not been differential, as the authors infer; actually relatively more gangue than sulphide has been slimed in the case of silver, gangue and sulphide have been substantially equally slimed in the case of zinc, and only in the case of the lead has sulphide been slimed more than gangue; even here the differential is small. On the other hand, there has been impoverishment of the sizes from 20-mesh to 200-mesh inclusive, which are the sizes in which table concentration is most effective in making the differential separation required on this ore.

12. Rod mill *vs.* ball mill

These machines are in competition throughout their range of crushing ability; both can, if forced to do so, take 3- to 4-in. feed and both can, in closed circuit with a mechanical classifier, produce −100-mesh product. But, while the ball mill may, under certain circumstances, justify its use on such coarse feed and may, at the other end of the scale, successfully compete with pebble mills the rod mill has, by common consent, failed to handle feeds coarser than 1-in., or at the coarsest 1.5-in., or to grind finer than 48-mesh. This is to be expected from consideration of the crushing bodies. There is little free fall of rods and hence insufficient impact to break large particles, nor is there, except near the bottom of the load, sufficient force (weight) to crush these particles by roll action. The amount of fine grinding done is a function of the extent of surface of the crushing media. This is much less in the rod than in the ball mill, for a given weight of charge, and therefore the amount of fine grinding is less. The weight of a single rod, or of a superincumbent layer transmitted through a single rod, is more distributed than is the case with balls; in consequence the crushing force is less and there is less tendency to crush large particles or to grind small ones very fine. Furthermore, while the ball mill may, with strong claims to economy, be used for one-stage reduction through a considerable range, as at INSPIRATION, the rod mill works much more efficiently when the reduction per step is small. But in the intermediate size

range, taking, say, −1-in. feed and delivering anywhere from 8- to 48-mesh product, averages based on Tables 4, 5, 11 and 50 indicate that the rod mill grinds about twice as many tons per horsepower-hour as the ball mill; that liner wear in the rod mill is about 60 per cent. that in the ball mill and rod wear about 75 per cent. of ball wear (based on high-carbon steel in both cases). Rods normally cost less than balls of the same material. Capacity per square foot of mill floor space required for the installation favors the ball mill slightly, but not enough to be an important factor in the comparison. Handling rods to and into the mill is somewhat less convenient than handling balls and the rod mill should be opened for inspection and the charge picked over the more frequently. The product of the rod-mill is not so sensitive to changes in feed rate as that of the ball mill, if accidental oversize is undesirable, as in preparing table feed, but the ball mill is the less sensitive to changing conditions when preparing flotation feed. Consideration involving the performance of the two types of mill on a particular ore, causes the conclusion to fall one way or the other, according to the ore and to the type of ball mill.

At Consolidated Mg. & Sm. Co. of Canada, Kimberley mill, a 5 × 10-ft. rod mill crushed 625 tons daily from − 1-in. to 14 per cent. + 28-mesh (and 28 per cent. − 200-mesh) with 72 hp. and a rod consumption of 0.46 lb. per ton. Compared with the 8-ft. × 48-in. conical ball mills at the same plant (see Table 11) the number of tons ground per horsepower-hour open-circuit (0.35) was greater than in the conical mill (0.29). Ball consumption was 0.273 lb. per ton. The conical-mill product was finer, which lessened the load on the re-grinding (second-stage) mills.

The following comparison between conical ball mills, Marcy ball mills and Cole-Bergman rod mills is based upon crushing hard quartz and diorite with rod mills, crushing the same ore with Marcy mills, crushing soft porphyry ore in Marcy mills and in conical ball mills. The hard ore was crushed from − 1-in. to the size shown in Table 52 in two 5 × 10-ft. rod mills in series, the first crushing to approximately 10-mesh in open circuit, the second finishing in closed circuit. The 10-mesh product was roughed on tables between the two stages of grinding. The same ore, coarse-crushed to the same size (− 1-in.) was ground in 8 × 6-ft. Marcy ball mills to the size shown in Table 52. Comparative costs, based on crushing 55,000 tons in the rod mills and 29,000 tons in the ball mills are shown in Table 53. The

the soft ore and the rod mill, crushing the hard ore. With these, and particularly with the rod mill, is compared an estimate of the cost of crushing the hard ore in the conical mill. This table indicates that the cost of crushing and grinding the soft ore with the conical mill is $0.02 per ton less than with the cylindrical ball mill; that rod-mill grinding of the hard ore is distinctly cheaper than Marcy ball milling, and that the difference between rod mills and conical mills on the hard ore is too small to be conclusive on estimate.

At Mill No. 4 of Federal Lead Co. an 8-ft. × 30-in. conical ball mill and a 4 × 9-ft. rod mill are working on somewhat different feeds (see Table 55). Under these circumstances the

Table 55. Comparison of conical ball mill and rod mill at Federal Lead Co.

Mill	8-ft. × 30-in. conical	4-ft. × 9-ft. rod	Ratio: conical ÷ rod
Size of feed	3% + 10-mm.	6% + 6-mm.	....
Tons crushed per 24 hr.	855	460	1.86
Tons per horsepower-hour, total feed	0.302	0.291	1.04
Tons per horsepower-hour of − 10-mesh produced	0.178	0.119	1.49
Tons per horsepower-hour of − 20-mesh produced	0.166	0.109	1.52
Tons per horsepower-hour of − 60-mesh produced	0.103	0.058	1.77

tonnage of feed passed through the mills per horsepower-hour is substantially the same, but the tonnage ground to any given mesh per horsepower-hour is distinctly in favor of the ball mill and increasingly so as finer sizes are investigated. Ball consumption per ton is half of rod consumption.

Forrester-Rexman mill (Fig. 26) is a cylinder 4 to 5 ft. diameter by 4 to 5 ft. long, trunnion-fed and discharged through fine screens at the ends with peripheral lifters in the mill shell for oversize return. It is run at about 28 to 36 r.p.m. according to diameter. The grinding media are rods cradled in the quadrants of the mill, supported on spider arms which are suitably protected by renewable liners. The mill is provided at each end with a drum feeder and a spiral in the trunnion, which delivers feed to the center of the mill

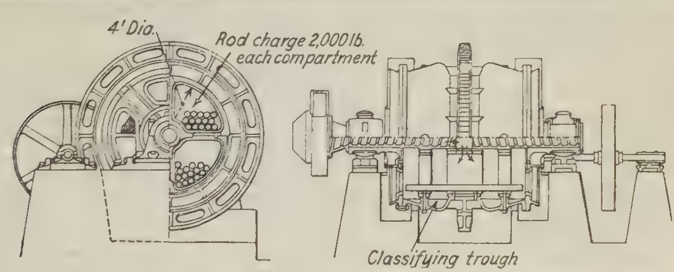

FIG. 26.—Forrester-Rexman rod mill.

whence it is delivered successively, due to the rotation of the mill, to one after another of the rod groups and the screen until it is finally crushed fine enough to pass the screen and leave the mill. With the rod load divided as illustrated the amount of power required to drive a given weight is claimed to be only about 25 per cent. that in the ordinary rod mill. On the other hand, it is very probable that the crushing effect per rod is less. The mill has not had sufficient use in metallurgical plants to furnish reliable data as to performance.

Allen (*113 J 987*) gives the following data of a test run on a 4 × 4.5-ft. mill. Weight of mill, 19,400 lb. Rod load, 8562 lb. @ 2½-, 2¾- and 3-in., 36 r.p.m. Feed: granite, −0.5 + 0.12-in. Product all through 0.06-in. (10-mesh). Feed rate, 182 tons per 24 hr. Power consumed, 19.5 to 21 hp. This is at the rate of 4.6 to 4.9 hp. per ton of rods and 0.38 ton per hp.-hr. crushed to 10-mesh. This performance is about the same as that of the ordinary type of rod mill (Table 50).

PEBBLE MILLS

Pebble mills are of the same general nature as ball mills but differ from them in that rock fragments instead of metal bodies are used for the crushing medium. Since pebbles are lighter than balls, the crushing effect of the tumbling mass in a pebble mill is less than in a ball mill, feed must be finer, and capacity and power consumption for a given size of mill are less.

There are two types of pebble mill, *viz.*: the cylindrical mill or tube mill and the conical pebble mill (Hardinge).

13. Tube mills

General. Tube mills were the forerunners of center-discharge ball mills. They were adapted from cement practice into cyanide practice, and from cyaniding were taken over into concentration shortly before the adoption of flotation. They are used for finer grinding than ball mills. This end is accomplished by increasing the length of the mill. At the same time, being used on finer feeds than the ball mill, it is unnecessary to have as great diameter or as heavy grinding media. The standard tube mill, so-called because of its substantially uniform adoption in South African cyanide practice, is 5-ft.

6-in. diameter by 22-ft. length inside the shell. The development of the tube mill in concentration plants has been toward a shorter mill of somewhat greater diameter. This is a logical development of the more perfect methods of classification that have been developed. Originally it was necessary to finish the grinding in one passage through the mill. When this is done, great length is necessary, notwithstanding that the great bulk of the grinding is done in the first few feet of the mill as shown in Fig. 27.

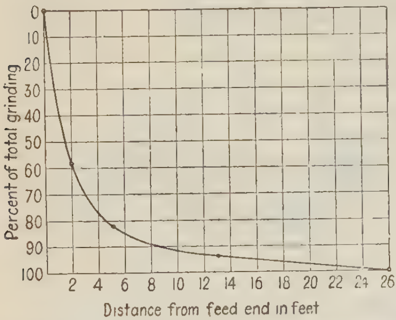

FIG. 27.—Amount of grinding at different points in a 6 × 22-ft. tube mill, dry-grinding talc.

Shell of tube mills is made of ⅝- to ¾-in. steel plate with double-riveted butt-strap joints. Rarely the joints are welded. Cast-iron flanges for attachment of heads are double-riveted to the ends of the shell after which the latter is swung in a lathe and the bases of the flanges are accurately machined at right angles to the shell axis. Bolt holes in the flanges are drilled by jig. Manholes, 13 to 15 × 18 to 20 in., are cut in the shell on opposite sides near the ends and fitted with cast seats for the manhole cover.

Heads are made of cast iron, about 1½ in. thick at the edges and thicker at the center, heavily ribbed, usually with the trunnion cast integral. After attachment to the shell the best practice is to swing the shell in a lathe and turn the trunnions true to the axis of the shell. Where this is not done it is difficult to bring the axis of the trunnions coincident with the axis of the mill and as a result the mill does not revolve truly and additional strain is brought onto all parts. The feed trunnion should be 9 to 12 in. inside diameter with 3- to 3½-in. walls and the length should be sufficient to give a bearing pressure of 100 to 150 lb. per sq. in. of projected area. The discharge trunnion of overflow mills is usually 4 to 10 in. greater diameter than the feed trunnion to afford gradient for pulp flow.

Linings for tube mills (see also ball-mill linings, p. 346) are of many varieties including iron or steel plates, silex, ironite, El Oro, Komata, Osborn, Forbes, Britannia, and many other types less well known.

Plate linings are made of hard white cast iron, cast steel, manganese or chrome steel with smooth or ribbed surfaces. Thickness is usually from ⅞ to 1¾ in. Plates give the largest possible internal diameter in the mill with consequent greater capacity and efficiency throughout the life of the liner. Smooth white-iron plates, 1¼ in. thick, 8 in. wide and 48 in. long in a 5 × 22-ft. mill taking 2½-mesh feed at the BUTTERS VIRGINIA CITY mill lasted 9 months, which was as good as the El Oro would do and the plate lining was the cheaper. (*89 J 905.*) At RAINBOW mill (*99 J 1104*) the 1½-in. cast-iron feed-end liner lasted 6 months. The discharge-end liner lasted longer; 1½-in. side liners lasted 13 months. Re-lining required 14 hours.

Ribbed plates allow less slip of the pebble load than smooth plates and are more suitable for coarse feed. They are sometimes made reversible, so that when one side of the ribs wears and the lifting effect is lessened the other side can be turned up.

Jones (*52 A 95*) says that in tube mills at TONOPAH BELMONT manganese-steel liners cost $0.064 per ton and lasted 16⅓ months while hard white iron lasted about 2 years and cost only $0.0173 per ton. Addition of new ribs to the manganese liners increased the life 10 months and decreased the cost to $0.0457 per ton.

Silex lining is composed of blocks or bricks of hard flint, normally 8 in. long, 4 in. wide, and from 4 to 7 in. thick. Uniformity in thickness is the important requirement, considerable variation in length and width are allowable. They are cemented into the mill with Portland cement. Joints are staggered to prevent circumferential grooving. Re-lining a 5½ × 22-ft. mill on the Rand has been done in 18 hr., but the usual time is 24 hr. from stopping to re-starting, including 4 hr. steaming. (*RMP.*) The cost of installing silex lining (4 × 4 × 8-in. blocks) in a 5 × 18-ft. mill at TONOPAH BELMONT in 1913 (*52 A 112*) was: Silex, 12,300 lb., $258; cement, 33 sacks, $36; labor, $102; total, $396. Silex lining

can be worn down to 1½ or 2 in. before it is necessary to replace it. Average life on the Rand was from 60 to 150 days, depending on the thickness and the conditions of operation. At the TREASURY MINE (*So. Af. Ass'n Eng'r's, Apr., 1905*) silex lining lasted 2½ times as long as smooth cast-iron and cost half as much. With thick blocks, which have the longer life, the diameter of the mill is materially decreased when the blocks are new as compared with the diameter when the blocks are old and there is consequently a marked change in peripheral speed of the mill during the life of the liner. With a new liner, horsepower, pebble capacity, grinding capacity and grinding efficiency are less than with a worn or thinner liner. It is necessary, therefore, to balance the cost of more frequent renewals attendant upon the use of thinner blocks against the decreased efficiency in the early part of the life of thick blocks. To compensate for greater wear at the feed end one plant (*7 JCM 368*) lined the first 7 ft. with 8-in. block, then 7½-in. for 1 ft., 7-in. for 1 ft., and 6-in. for the balance of the length. IRONITE is similar to silex, except that the material used consists of blocks of hard trap rock. In some localities where hard, close-grained rocks are obtainable locally, these are used in place of silex. Silex was more generally used than plate liners. The principal DISADVANTAGES of the stone-block type of liner are the great reduction in mill volume and the variation in volume, power consumption, capacity and efficiency between new and old liners. These are sufficient to bar such liners in most modern plants.

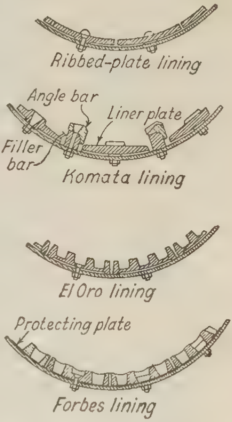

FIG. 28.—Liners for tube mills.

El Oro, Forbes and Komata liners are most used in American mills. El Oro liner is shown in Fig. 28. It consists of grooved plates bolted to the shell of the mill, the width of the grooves being about the medium dimension of the larger pebbles used. In operation these larger pebbles wedge into the grooves and the liner surface soon becomes an irregular one of pebbles that protect the metal ribs from wear. As pebbles wear down and are broken they fall out and are replaced by other pebbles. El Oro liner plates are made of cast iron, cast steel, or special steels.

Osborn liner (Fig. 29) is a modification of the El Oro in which hard-steel ribs are wedged into place by mild-steel wedges, both being set in cement mortar. There are no bolts. Pebbles fill the spaces between the ribs and take most of the wear. This liner has displaced all others in South Africa. At SIMMER AND JACK (*RMP*) a mill with Osborn liner had a duty of 139.5 tons containing 57.2 per cent. − 90-mesh while an adjoining silex-lined mill ground 133.5 tons per day to 54.6 per cent. − 90-mesh. Ribs wear most rapidly at the fed end and after initial wear at this end are reversed. Sectional bars (three lengths to a course) permit more economical replacement for head-end wear. Life is about 300 days. One man can re-line in 12 hr. (*97 J 465*).

Erect plates 4 in. deep, tapering from 1¾ in. to ¾ in. in width; wedge bars 2½ to 3 in. wide and ½ to ¾ in. thick. (*52 A 42*).

FIG. 29.—Osborn liner.

Forbes lining (Fig. 28.) is the same in principle and similar in appearance to the El Oro lining. It differs from the El Oro in that the plates are cast in the form of a curved grid and are bolted against a back plate that protects the shell at the bottom of the openings in the grid. Life at NEVADA PACKARD in a 6 × 10-ft. mill making 75 per cent. − 200-mesh was 345 days compared to 220 days for a step liner of approximately the same weight.

Globe lining (*98 J 393*) is of the general El Oro type but with circumferential grooves tapering toward the base and also tapering longitudinally in a direction opposite to the direction of rotation. The original pebble load should be a good mixture of all sizes in order to insure quick filling of the liner grooves. Life at HOLLINGER is reported as 3 months greater than that of El Oro lining. Weight of metal for a 5 × 20-ft. mill is 15,500 lb. Re-lining requires 6 men 12 hr.

Komata lining is substantially a ribbed-plate lining with replaceable ribs. See Fig. 28. It was first introduced in New Zealand and is now used almost exclusively there both for pebble charges and for ball charges up to 3-in. size, both wet and dry grinding (*24 CMI 192*). It is made up of plate liners alternating with rib liners about 18 to 20 in. apart. The rib bars are made up of two parts, a cast-iron base and a special steel wearing top that is reversible and readily replaceable. In one type (wedge-bar) the rib bars are wedge-shaped and hold in the plates so that the number of bolts is reduced. Plates are ⅜ in. thick at the edges

and 1 in. at the center. Maximum wear comes on the angle bars and the use of separate wearing parts effects a considerable economy in the amount of metal that must be discarded. Raised bosses are provided around the bolt holes to prevent cupping, and joints in the bars are staggered to prevent circumferential grooving. With cast-iron plates a low boss is put on the back to protect the plate against breakage when the bolts are tightened Brown, the inventor, recommends (*104 P 206*) lower speed and lower pebble load than with smooth liners of the El Oro type on account of the greater lifting effect of the ribs. He cites (*104 J 177*) a competitive test between Komata and El Oro liners in 4½ × 20-ft. mills. First cost was about the same. Metal wear was much less with the Komata and power consumption slightly greater. Sizing tests are given in Table 56. The Komata appears

Table 56. Comparative grinding with Komata and El Oro liners

Screen, mesh	Weight, per cent.			
	El Oro		Komata	
	Feed	Product	Feed	Product
28	14.6	0.6	18.5	0.1

to have been slightly better in producing material down to 150-mesh but the El Oro produced slightly more −280-mesh material. At TONOPAH BELMONT (*52 A 112*) Komata manganese-steel lining cost (1913) $1785 installed, including $145 for labor. After 16⅓ months new ribs were put in at a cost of $273 and lasted 10 months, when the whole lining was removed. Cost per ton ground for this lining was $0.0457. A locally-cast hard white-iron ribbed liner costing $712 in place lasted about 2 yrs. and cost $0.0173 per ton. Silex (4 × 4 × 8-in. blocks) cost $396 in place and lasted 8 months, making the cost $0.0583 per ton ground.

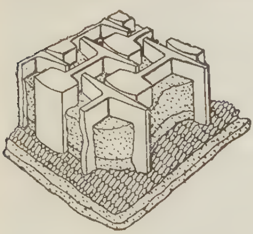

FIG. 30.—Britannia tube mill lining.

Britannia lining (Fig. 30) consists of 3- to 4-in. pieces of old railroad rails set on end in cement. Line the mill in sections as follows (*99 J 239*): First spread a layer 1 in. thick of cement mortar (1 cement to 2 of sharp, clean sand), press down sections (not to exceed 1 × 2 ft.) of 4- to 8-mesh wire screen, then a second 1-in. layer of mortar into which the rail ends are forced as far as possible, then more mortar to within 1 in. of the top of the rails. Allow to set, then turn the mill to line another section. When starting up, run for a few hours with lump ore but no balls or pebbles to allow crevices to fill. Cement wears sufficiently more rapidly than steel so that the ends of the rails project and make the lining surface irregular.

Barry lining consists of silex blocks cemented into a sectional iron honeycomb. Comparative performances of the Barry and Komata liners at the TALISMAN mine, N.Z., in two 4 × 12-ft. mills running side-by-side are shown in Table 57. Neither mill did good work but the mill with Komata lining produced 6.8 tons of −60-mesh material per 100 tons of feed in open circuit against 4.8 tons in the other mill. At 100-mesh the corresponding produc-

Tons −100-mesh produced per 100 tons feed	0.1		2.7	

tions were 2.7 and 0.1 tons per 100 tons respectively (*16 Aa 366*). The Barry has the distinct disadvantage, in common with all cemented liners, that a large part can fall out, with subsequent wear on the shell, and no warning given to operators. Leakage at bolt holes usually warns of breaks or wear-throughs in the case of plate or plate-and-rib liners.

Plymouth lining (*101 J 263*), shown in Fig. 31, is made of pieces of semi-steel battery liner, roughly 4 in. wide and 12 to 36 in. long, and pebbles, cemented in as shown.

Fig. 31.—Plymouth lining.

Rubber liners have been tried at the Nipissing mill. A 4 × 20-ft. ball-tube mill carrying 20 tons of 1¼-in. cast-iron balls and lined with ⅝-in. vulcanized rubber sheet with two layers of fabric was run in regular re-grinding service from Jan. to Aug., 1923, at which time, after study of the data, Parsons (*116 J 489*) reported as follows: Feed, −60-mesh, 40 to 80 per cent. −200-mesh sand; product, substantially all −200-mesh. Moisture, 44 per cent. Speed, 32 r.p.m. Change from ½-in. smooth-iron liners to ⅝-in. rubber increased slime-making capacity 15 per cent. and made it possible to shut down one of the primary 6 × 20-ft. tube mills and reduce the speed of the rubber-lined mill from 32 to 28½ r.p.m. The 4 × 20-ft. mill, rubber-lined, produced 11 per cent. more −200-mesh material from −4-mesh stamp-battery product than was produced on equal tonnage by a 6 × 20-ft. iron-lined pebble-charged mill running in parallel with it. Cost of ⅝-in. rubber liner for a 4 × 20-ft. mill is somewhat less than that of a 2-in. chilled cast-iron liner and the weight of the rubber is about 5 per cent. that of the iron. The relative life of the two was not determined but it was indicated that rubber would probably outlast iron on −4-mesh feed. Re-lining with rubber is easier and quicker than with iron. Ball consumption is less with the rubber liner.

Another rubber liner was tried in a ball mill, but was vulcanized too hard and wear was excessive.

Rubber lining has also been tried in Rand tube mills (*118 J 490*) with distinctly encouraging results. Wear conditions are harder than at Nipissing on account of the coarse, hard, sharp-edged lumps charged for grinding media and it was found that a soft pure rubber was better than a vulcanized composition. Cost of liner 1½ in thick, which thickness is contemplated from a structural standpoint, is estimated at about $4000 against $800 for 4-in. iron liner in a standard (5½ × 22-ft.) mill, but the life of the rubber is estimated at 2 years against 6 months for the iron. At Sandusky Cement Co. (*B. W. Rogers, 1925 meeting, Portland Cement Ass'n*) smooth and wave-type rubber liners were tested against smooth-iron liners in 5 × 22-ft. tube mills charged with balls, grinding cement slurry in a

pulp containing 60 to 65 per cent. solids. The feed was all − 4-mesh. Results are given in Table 58.

Table 58. Rubber vs. iron liners in tube mills grinding cement

Kw.-hr. per ton	14.9	14.9	16.2	13.5	9.8	11.6	11.1

For further data on wear of various types of liners see Tables 65 and 77.

Head liners are made of the same material as shell liners. Wear of end liners is frequently much greater than that of the shell liners. See notes (*ag*), (*ay*) and (*bv*), Table 65, and data on HOLLINGER performance, p. 437. Allen (*106 J 867*) warns against unsuitable liners and shows (Fig. 32) a wrongly- and a rightly-designed liner. The first wore through at the junction of the trunnion and head liner, grit and sand worked in behind and scoured until the mill collapsed by failure of the trunnion. This possibility was prevented in the re-designed (second) form.

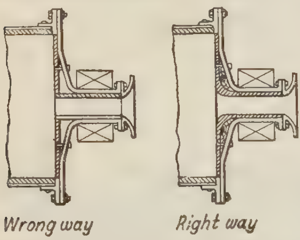

FIG. 32.—Tube-mill head liners.

Porcelain and wood blocks have been used in special instances for liners.

Choice of liner. The type of liner used depends to a considerable extent upon the character of the feed. When the feed is relatively coarse and relatively coarse product is desired, the rough-surface liners, such as the El Oro, Komata, or ribbed-plate are used; with finer feeds, or where an extra fine product is desired, silex or metal-plate liners are used. A smooth-iron liner will give the finest product and lowest power consumption for a given mill speed; a rough liner will give higher capacity unless the finished size is very fine. Comparison involves consideration of the ability to produce the material desired, life, effect on capacity, time to re-line and power consumption, as well as initial cost.

Grinding charge is composed ordinarily of flint pebbles in sizes varying from 2- in. to 6-in. The best flint pebbles come from the seashore in Denmark. Inferior imported flint pebbles come from France. French pebbles are usually light brown to gray on fracture compared to dark brown to black of the Danish pebble. Newfoundland pebbles are graywacke. They are hard but break readily. Pebbles range from 1- to 7-in. diameter and are graded by number as in Table 59. The characteristics of a desirable pebble are: (*a*) shape as nearly spherical as possible; (*b*) toughness; *c*) hardness; (*d*) high specific gravity; (*e*) chemical composition that is harmless in the mill product; (*f*) low cost. In using imported pebbles the first cost is usually only a small part of the total cost, hence it is economy to buy the best. In 1915 the best grade cost $11 per ton ready

for export, \$15 per ton *ex* steamer New York, about \$35 at Tonopah, Nevada, and \$62.50 at Round Mountain, Nevada, 72 miles from Tonapah by wagon road (*110 P 139*). No domestic source of pebbles yields a product as good as the imported variety.

At the West End mill (*110 P 139*) artificially-rounded (tumbled) locally-mined flint was consumed in a mill with smooth-iron lining in the proportion of 1.05 to 1 of Danish pebbles in a mill with Komata lining and the cost per ton ground was only ⅐ of the cost of imported pebbles. Local pebbles wore flat and occasionally stuck in the grate. At Hedley Gold Mining Co. (*114 J 1057*) Danish pebbles at \$33 per ton delivered cost, on the average, \$2600 per month. Substitution of local pebbles at \$4 per ton cut the cost to \$600 per month.

In localities where freight charges on imported pebbles are excessive, lumps of local hard rock or hard ore have been used for grinding media. The advantage of this procedure is the apparent small cost of the material. The disadvantages are, however, several. Grinding is likely to fall off because the angular shape of the particles when first introduced is not good for grinding and because the pieces tend to wear flat and flat shapes are not so good as rounded.

But Graham (*7 JCM 317*) reports a competitive test in a Rand plant between mills loaded with banket and with Danish pebbles in which, with split feeds, the product of the former contained 9.7 per cent. +60-mesh and 64 per cent. −90-mesh against 11.3 per cent. +60-mesh and 61.4 per cent. −90-mesh for the latter. Bevington (*7 JCM 368*), discussing Graham's paper, agrees with his conclusions as to relative grinding efficiency and also with a conclusion that the banket is less destructive of silex lining. Allen (*105 J 1034*), tested Danish flint against roughly-rounded local felsite. His results are given in Table 60. The

felsite was much cheaper per ton of pebble and, therefore, per ton ground. He also tested the felsite against quartzitic mine rock and found (Table 61) that the felsite ground more material and that less was consumed. Breakage is likely to be excessive, resulting in formation of small angular and flat pieces which do little or no grinding and themselves are liable to further breakage.

When hand picking is already practiced the pebble material may be selected at little or no cost, but frequently a special operator must be put on for this purpose. His capacity will be 15 to 20 tons per day when picking from a belt,

if the supply of material is plentiful, much less under any other mode of selection. Handling from the sorting place into the mill need be no more expensive than the handling of imported pebbles, per unit weight, and may be even less if special provision is made, but the consumption of local materials may run up to well over 100 lb. per ton of ore ground, so that the handling cost per ton of daily capacity will usually be much higher than with pebbles. Large consumption causes corresponding decrease in capacity of the mill and the feed to the balance of the plant is materially diluted by the introduction of barren material. Recovery may also fall off. Quartano (*91 J 1017*) says that mine rock does not wedge into ribbed linings as well as flint pebbles and that liner wear is correspondingly higher. He suggests the daily addition of some flints to furnish liners and says that they will be selected by the mill, and that apparent economy may be gained by this practice in certain cases.

Comparative pebble consumption per ton ground	2		1	

Pebble charge is ordinarily carried at slightly above the mill axis, averaging perhaps 55 per cent. of the total internal capacity. The weight of pebbles for this charge is given roughly by the equation $W = 40\ D^2L$, where W = weight of charge in lb., D = nominal diameter of mill in ft. and L = length of mill in ft. For a charge of any depth, the weight W per ft. of length, in a mill charged up to or below the axis, is given by the equation

$$W = 4Vw/3\sqrt{(0.626V)^2 + V(2R - V)},$$

where V = depth of charge in ft., R = radius of mill in ft., and w = weight of charging material in lb. per cu. ft., struck volume. This is 100 to 105 lb. per cu. ft. for pebbles and 300 to 325 lb. per cu. ft. for iron or steel balls. If the top of the charge is above the axis, take V as the depth of the uncharged portion and deduct W from the weight for a cylinder of radius = R, and length = 1, fully charged.

Burt and Caetani (*37 A 3*) concluded that efficiency increased with increasing pebble load. On the other hand at Belmont Shawmut mill (*121 P 660*) it was found that although there was no change in grinding, there was an increase in power consumption corresponding to decrease in pebble volume and that consumption of Danish flint pebbles in a 5 × 18-ft. mill was 0.3 lb. per ton in grinding −10-mesh feed to 4 per cent. on 48-mesh, 56 per cent. −200-mesh, when the pebble load was carried 10 to 12 in. below center line, while with the pebble load at the center, consumption was 1.3 lb. per ton. Decrease in consumption was gradual with decrease in charge.

Testing tube-mill pebbles. A large part of pebble consumption is due to chipping, which occurs principally at the feed end of the mill. This has a double disadvantage because it reduces the size of pebbles at the point where maximum size is desired and also makes it necessary for the chips to pass the full length of the mill before they can be discharged, and so consumes considerable power in grinding. Allen (*105 J 1033; 124 P 405*) contends that toughness is the important property of suitable pebble material and that a tough soft rock may be superior to a hard but brittle flint. He cites the test given in Table 61 in support of this contention. " Mine rock " was a hard but friable quartz. The felsite was comparatively soft, but tough. Both were hand picked and roughly cobbed.

Allen suggests testing pebbles for hardness, toughness, and abrasion by the method practiced for testing road material. The hardness test consists in measuring the dimunition in weight of a standard cylinder of rock (about 25 mm. diam. by 100 mm. long) when abraded against a revolving steel disk, using quartz sand as the abrasive, the pressure against the disk and the number of revolutions thereof being constant for all tests. An arbitrary coefficient of hardness is obtained by dividing the loss in weight, expressed in grams, by 3, and subtracting the result from 20. The range is from 19.7 for the hardest varieties of quartzite to 0 for very soft limestones and sandstones.

Toughness is tested by measuring resistance to impact. A cylinder of rock with plane ends is placed in an impact machine and subjected to the blow of a 2-kg. weight falling from increasing heights varying by 1 cm. The height in cm. of the last blow preceding the breaking blow is taken as the toughness coefficient. The experimental range with different rocks is from 2 or 3 to 60.

Resistance to abrasion is tested by tumbling 50 pieces of uniform size, averaging about 100 gm. each, in a cast-iron cylinder 20 cm. inside diameter revolved 10,000 times at 30 r.p.m. The material is removed from the mill after tumbling and sized on a 16-mesh screen and the oversize weighed. The percentage loss in weight is called " Per cent. of wear," and 40/" Per cent. of wear " = " FRENCH COEFFICIENT OF WEAR." French coefficient varies for different specimens from as low as 1 to as high as 40, the higher figure indicating the least abrasion, *i.e.*, the greatest resistance to abrasion.

Table 62. Wearing characteristics of rocks (toughness 18 or over). (*After Allen*)

Rock	Samples tested	Abrasion, " French coefficient "			Hardness, average
		Low	High	Average	
Quartzite	14	7.8	24.5	17.5	18.7

Schist	5	8.5	31.7	19.6	18.4
Granite	1	...	...	25.3	18.9
Dolomite	1	...	...	7.4	18.2

Table 62 gives abrasion and hardness coefficients on a variety of rocks having a toughness of 18 or over. After study of a large number of tests Allen concludes that for pebble-mill work toughness should be more than 18, that the French coefficient should not fall below 16, and that, these coefficients being equal for two rocks, the one with the greater hardness coefficient will make the better pebble. For detailed procedure in testing see *Bull. 347, U. S. Dept. Agriculture.*

Hotchkiss (*104 J 288*) reports competitive abrasion tests on imported flints and Baraboo (Wis.) quartzite pebbles in which the quartzite showed considerably greater resistance. There are no corresponding tests of behavior in actual tube milling.

Pebble consumption varies according to the kind of pebble, hardness of the ore, size of feed and product, type of liner, pulp dilution and total feed rate. When mine rock is used, the consumption ranges from 15 to 200 lb. per ton of feed. With flint pebbles the average, according to Table 65, is about 2 lb. per ton and the range from 0.5 to 8.0. Hard ore, naturally, causes greater consumption than soft. Coarse feed consumes more than fine.

At West End mill (*110 P 139*) feed was battery product through 0.27- and 0.19-in. screens, hard but not tough quartz. Mill product was 80 per cent. – 200-mesh. Pebble consumption averaged 7.1 lb. per ton; range was from 4.8 lb. with the finer feed and Danish pebbles to 8.7 lb. with coarse feed and French pebbles. Consumption at three other mills in the district taking finer feed and finishing to the same size was 4.2, 4.4, and 4.7 lb. per ton.

Fine grinding consumes more pebbles than coarse, as is quite consistently indicated by Table 65. Consumption in closed-circuit grinding is greater than in open-circuit work, as a general thing, but it is probable that this is due to the fact that the product of closed-circuit work is generally the finer. Ribbed liners cause higher pebble consumption than smooth on account of the greater tumbling that they produce. High moisture content causes high pebble consumption. Consumption per ton of initial feed is lower the greater the circulating load. Table 63 (*98 J 471*) illustrates this fact.

Table 63. Effect of total mill tonnage on pebble consumption. (*After Mishler*)

Tons initial feed per 24 hr.	26.1	40.3	42.0	50.0
Tons total feed per 24 hr.	35	80	85	200
Pebble consumption, pounds per ton	127.9*a*	15.8	15.3	8.2

a Includes 110 lb. of local hard rock.

At Miami (*47 A 54*) it was found that increase in length of cylinder of a 6-ft. conical pebble mill decreased pebble consumption by nearly 50 per cent. It was also found that pebble consumption was dependent on size of feed, amounting to 1.85 lb. per ton on – 2.5-mm. feed against 3.60 lb. with – 6.5-mm. feed.

Small iron balls (BALL-PEBS) have replaced pebbles in tube-mill practice in some plants with marked increase in capacity. The change usually requires change of liners and change in drive to transmit the additional power, or the mill must be run with an undercharge of balls. Increase in capacity is roughly in proportion to increase in power consumption. See Tables 84, 86 and 87. Substitution of balls for pebbles must be carefully made, however, because of the considerable increase in strain on the mill, the shell and bearings of which were designed for a pebble load.

Feeders are of three general varieties known respectively as scoop, elbow and squirt. The scoop feeder is of the spiral type, ordinarily one-way, similar in every way to ball-mill feeders except not ordinarily so heavily made nor of such large opening.

At Nevada Packard the scoop feeder has removable side plates which permits inspection of the spirals.

The elbow feeder consists of a flanged elbow leading into the trunnion and packed to prevent leakage. The squirt feeder is used to introduce relatively fine liquid feed from a classifier spigot or similar source and consists of a nozzle pipe passing through a stuffing box into the trunnion.

Discharge from tube mills may be of simple overflow (center-discharge) type, in which case the discharge-trunnion opening is frequently of larger diameter than the feed trunnion; or a quick discharge with sand elevator is used.

A slotted grate is frequently placed near the discharge end to prevent discharge of pebbles. The grate is usually placed in the mill proper close to the trunnion and is bolted to the shell. This makes it impossible to observe the inside of the mill and the grate wedges badly and is hard to remove.

Allen (Fig. 33) shows a form of trunnion grate that screws against the trunnion liner; it does not blind readily on account of the large peripheral discharge space (a) and is easily removed.

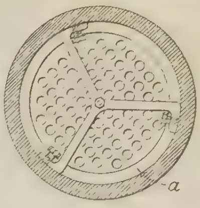

Fig. 33.—Trunnion grate for tube mill *(103 J 1072)*.

Scoop discharge is a quick-discharge mechanism for tube mills, consisting of a spiral placed between a grate and the discharge-end head of a tube mill. It picks up material discharged through the grate and delivers it through the discharge trunnion.

Graham *(16 JCM 59)* presents the data in Table 64 summarizing tests on mills with and without scoop discharges at City Deep Mill, Rand. The table shows that the tons of −90-mesh produced per horsepower-hour is substantially the same both with and without scoops and irrespective of the size of scoop, that capacity is greater with than without the scoop and greater with a scoop of large (58-in.) diameter than with a small (34-in.) one, but that pebble (and presumably liner) wear are greater with scoops than without and greatest with the scoop of greatest diameter. The conclusion from the tests is that if pebble and liner wear cost more per ton than the capital expense of additional mills, use the center-discharge mill, otherwise, the scoop mill.

An incidental advantage of the scoop discharge, which may become important in certain instances, is the fact that it permits the use of smaller discharge trunnions and thus saves head room. Mueller *(98 J 564)* commenting on his experience with quick-discharge mills grinding through 35-mesh at Cobalt, in open-circuit, condemns both diaphragm and quick discharge, the former on the ground of uselessness and the latter on the grounds that it discharges too much oversize and causes excessive pebble consumption. He admits the possible usefulness of the quick discharge in closed-circuit work with large circulating load. The quick discharge has also been used when it was wished to use the tube mill as a granulator for table feed *(99 J 694)*.

At Gold Hunter a 5 × 14-ft. mill with radial adjustable shutters ground 130 tons of jig middling per day in closed circuit with a 20-mesh Callow screen. The product contained 30 per cent. −200-mesh; power consumption was 39 hp.; pebble consumption, 0.9 lb. per ton. Without the quick discharge the capacity was 112 tons to 40 per cent. −200-mesh; power consumption, 33 hp.; and pebble consumption 1.2 lb. per ton.

A bell-shaped discharge lip, similar to that used in ball mills, and drip rings to prevent grit from working back into the discharge bearing are used in some cases. With open-end discharge it is common practice to fit the discharge bell with a trommel with ⅛- to ¼-in. screen which serves to separate wood chips and pebbles yet passes pulp readily.

Pebbles are fed by throwing them through the discharge trunnion of center-discharge mills. In other cases the discharge-trunnion liner has a reverse helix cast on the inner surface which serves to turn back pebbles and also to carry in pebbles fed through the discharge trunnion. In grate mills pebbles must be fed through the feed trunnion. This is readily done with scoop feeders but not so readily with the elbow type. When local rock is used for a grinding medium the tonnage necessarily fed is large and special provision is frequently made for charging.

Support. Tube mills are almost invariably supported at the head end by a trunnion bearing. The discharge end is supported by trunnion bearing or, less frequently, by tire

and rollers. Dowling (*RMP*) says that trunnion mills on the Rand have required less maintenance than tire-and-roller mills.

Drive problem is substantially the same as for ball mills (p. 349).

Bulkley (*54 A 137*), writing of SOUTH AFRICAN practice, says that belt drive to pinion shafts from 500- to 600-r.p.m. slip-ring motors with high starting torque (150 to 200 per cent. of full load) is usual and that with such a rig there is no necessity for a clutch or belt-shifting devices. Motors (250-r.p.m.) direct-connected to the pinion shaft through a flexible coupling failed through breaking down of the motor winding on account of vibration transmitted through the coupling. At NIPISSING (*48 A 16*) the belt from 125-hp. motor with 24-in. (diam.) pulley to the 96-in. pulley on the mill countershaft is 18-in. 8-ply endless rubber. The pulleys range from 19-ft. 4-in. to 24-ft. 4-in. centers horizontally on different installations in this plant. The belts were highly satisfactory and did not have to be cut or spliced in the first 12 months.

Setting up. For detailed instructions see Labbe, 101 *J* 777.
Manufacturers. Same as cylindrical ball mills (see p. 359).
Performance of tube mills is shown in Tables 65 and 65*a*.

At BELMONT SURF-INLET a 5 × 16-ft. mill in closed circuit grinds 80 tons per 24 hr. to 70 per cent. − 200-mesh for 60 hp. with a consumption of 0.6 lb. white-iron liner and 5- to 6-lb. Danish pebbles per ton. At HOLLINGER (*Bul. CMI, Mar. 1923*) two 6 × 16-ft. mills charged with 11 tons of pebbles each (5 in. above axis), running at 24 r.p.m. crush 300 tons each of new feed per 24 hr. to 70 per cent. − 200-mesh. The total tonnage is three times the original. Power consumed = 115 hp. each. Pebble consumption = 1.33 lb. of 4-in. flints per ton of new feed. Ribbed white-iron shell liners last 22 months; end liners, 16 months; cast-steel grates (3/8 × 3/4-in. slots) last 6 months. At the same plant 5 × 20-ft. tubes following the stamps crush 160 tons new feed per day to 70 per cent. − 200-mesh. Total tonnage is about 500 for each mill. Charge, 9 to 9.5 tons of flint pebbles to 5 in. above the mill axis; 28½ r.p.m.; 75 hp. for one mill and one Dorr classifier. Pebble consumption, 5 lb. @ 4-in. per ton of new feed. At NEW MODDERFONTEIN (*109 J 255*) 6 × 20½-ft. mills at 28 r.p.m. with Osborn liners and scoop discharges, in closed circuit with cones, grind 240 tons per day from − 3-mesh battery product to 60-mesh. Each mill has a 150-hp. motor.

14. Operation of tube mills

Capacity depends upon the physical character of the ore, the size of mill, size of feed and product, weight of charge and size of pebbles, speed, liner, and whether the mill is in closed or open circuit. The effects of the several variables are much the same as in the ball mill. (See pp. 387–409.) Table 66, which is generalized from Table 65 and from manufacturers' catalogs gives figures that are reasonably safe for estimating purposes on average ores.

James (*21 IMM 3*) gives a generalized figure for capacity of Rand mills of 10 tons per day per ton of pebble load or 1.5 tons per horsepower-day (0.062 ton per horsepower-hour) from − 3/8-in. to − 90-mesh. Ball's generalized figure (*21 IMM 3*) is 150 tons per 24 hr. to 60-mesh from a 5½ × 22-ft. mill drawing 75 to 90 hp., or 0.069 to 0.083 ton per hp.-hr. At EL ORO the capacity is about 1.2 tons per hp.-day (0.05 ton per hp.-hr.) from sand to 150- or 200-mesh. Gieser (*97 J 463*) gives 0.087 ton per hp.-hr. to 90 per cent. − 100-mesh on this ore and about the same when grinding from 7 per cent. + 60-mesh to all-through 200 mesh. Average tons per horsepower-hr. from Table 65 are: 0.179 grinding to table sizes (10- to 20-mesh); 0.073 ton per hp.-hr. to flotation size (48- to 65-mesh); and 0.040 ton to 100-mesh. Brown (*105 J 246*) says that a tube mill can safely be fed 0.75 ton per cu. ft. of mill volume per 24 hr., including classifier return. This figure, developed from cyanide milling, is low for flotation practice and low for the most advanced cyanide practice at the present time, but accords well with practice in older mills.

Character of ore has, in general, more to do with the grinding done in tube mills than in ball mills for the reason that tube-mill feed and product are normally both finer than ball-mill and the bulk of the work of the tube lies in

F Feed. *P* Product.

NOTES TO TABLE 65

a Italic numbers refer to column numbers in Table 65*a*. *i* White-iron tips. *l* Fixed amount added daily as calculated from tonnage and wear per ton. *m* One 5 × 8-ft. and three 5 × 14-ft. *n* Feed is classifier sand, all through 35-mesh, 90 per cent. +100-mesh; product of classifier, 75 per cent. −200-mesh. *o* El Oro, Komata and wave in different mills. *p* Mine rock, largely rhodonite. *q* Seven 5 × 16-ft.,one 5 × 20-ft., two 4½ × 15-ft., one 4 × 20-ft., eight 4½ × 20-ft. *r* Ten 4½ × 20-ft., one 5 × 20-ft., three 4½ × 15-ft. *s* Primary mills *4*, secondary *5*. Product in both columns is classifier overflow. *t* Primary mills *6*, secondary *7*. Product in both columns is classifier overflow. *u* Cascade and El Oro. *v* Primary mills, 6 months; secondary mills, 12 months; see also note (*s*). *w* Primary, cascade type, 5 months; secondary, El Oro type, 16 months. See also notes (*t*) and (*u*). *x* Primary mills have no grates. Secondary mills have baffles to hold back grinding media. *y* 6-in. in primary mills, 3-in. in secondary. *z* Classifier overflow is 1.5 per cent. +100-mesh and 78 per cent. −200-mesh. *A* Hard-iron and manganese-steel bars. *B* Average of 3-yr. operation: labor on repairs, $0.0036; supplies, $0.0044; liners, 0.0233; pebbles, $0.0771; total, $0.1084. *C* Screen test of feed (*F*) is a composite of original plus classifier return; product (*P*) is classifier overflow. *CI* Cast iron. *CCI* Chilled cast iron. *Cr* Chrome steel. *D* Leaky liner bolts. *DC* Dorr classifier. *DF* Danish flint. *E* El Oro ribs of hard cast iron, partially replaced after 133 days; consumption, 0.60 lb. per ton of mill feed. *F* Largely rhodonite and quartz. *FF* French flints. *G* Three 5 × 16-ft.and two 5 × 18-ft. Tonnage of new feed to 18-ft. mills = 80 per 24 hr.; total, 100 tons per 24 hr. *Gr* Grease. *H* 50-hp. motors on 16-ft. mills; actual power 66, 75 and 76 hp. respectively on the 3 mills. One 50-hp. motor on one 18-ft. mill draws 79 hp.; one 100-hp. motor on the other 18-ft. mill draws 84 hp. *I* Classifier feed all passes 3-mesh, 20 per cent. −200-mesh; classifier sand to tube mills; classifier overflow, 70 per cent. −200-mesh. *J* Local quartz and chalcedony pebbles. High consumption due to poor quality. *K* One 5 × 20-ft., seven 5 × 16-ft., eighteen 4½ × 20-ft., one 4 × 20-ft., arranged as the second and third steps in a 3-stage series of which stamps and Marcy ball mills in parallel are the first stage. *L* Dorr and Esperanza classifiers. *M* Feed is ball-mill and gravity-stamp discharge, all through 2-mesh. Product of secondary mill classifiers is 75 per cent. −200-mesh. *MC* Various types of mechanical classifiers, *e.g.* Dorr, Akins, Ovoca, Esperanza. *Mn* Manganese steel. *MR* Mine rock. *N* 40 per cent. of mill fall. *O* Oil. O_1 Classifier overflow, 80 per cent. −200-mesh. *P* Rolls, ball mill, tube mill, screens, and Dorr classifier tended by one man per shift. *Q* Power repairs, overcrowding of cyanide department. *R* Classifier overflow is 1 per cent. +100-mesh, 72.3 per cent. −200-mesh. *S* Classifier overflow is 0.5 per cent. + 48-mesh, 68.2 per cent. −200-mesh. *SS* Spiral scoop, one-way. *T* Inspection and re-lining. *U* 3-in. to 7-in.; weight, 7 to 16 lb. a piece. *V* Classifier overflow. *W* Tended by battery man. *WI* White iron. *X* Power shortage; re-lining. *Y* Cast-iron sole with plate sides. *Z* Repairing tires and rollers. *aa* Indefinitely long. *ab* See page 347. Same except that silex blocks replace quartzite. Consumption of silex, 0.16 lb. per ton; iron 0.097 lb. per ton. Material for 5 × 22-ft. mill: 900 @ 4½ × 5 × 8½-in. silex blocks, weighing about 13 lb each; 19 cu. ft. each Portland cement and fine sand; 10 rows cast-iron ribs, 47½ in. long 4½ in. deep, 2 in. at base tapered to 1¾ in., weight 110 lb. each. Two men line the mill in three shifts. One shift for lower half, one shift live steam, one shift cooling with draft; then one shift for ¼ of lining followed by the same drying and cooling; then one shift for the final ¼, followed by 12 hours' steaming after which the pebble load is put in and the mill started. The addition of soda ash to the mortar hastens setting and permits the mill to be put into use in 8 or 10 hr. The use of the iron ribs has greatly lengthened life of lining. Present life 2½ to 3 years (*102 J 27*). *ad* Inspection and changing grates. *ae* 365 and still good. Hard white-iron lifter bars last 9 months. *af* Adamant blocks (quartzite cubes) from Iowa and pebbles from California are a fair substitute for Danish pebbles. The consumption is almost twice as great but the cost per ton ground is about the same. *ag* Shell is lined with cast-iron plates and filler bars and manganese-steel lifting bars. ⅝ × 7-in. ship-lap false liners used between the shell and the shell liners. The outer circle of the end liners is Forbes type with flint cubes concreted in, all backed by ¼-in. boiler plate. The inner circle end liners are cast iron. Trunnion liners are manganese steel. Life of shell liners, 450 days; Forbes-type end liners, 430 days; feed-end inner circle, 210 days; discharge-end inner circle, 600 days. Discarded high-carbon-steel roll shells, approximately 1¼ in. thick, when cut and shaped to replace cast-iron shell liners, have double the life of the latter. *ah* Two 7 × 10-ft. and one 7 × 12-ft. Data refer to both. *ai* Anaconda classifier and bucket elevator. *aj* Classifier overflow is 1.3 per cent. +20-mesh, 18 per cent. − 200-mesh. *ak* Three mills and two jigs operated by one man. *al* Once a week through man-hole. *am* Loaded to keep ammeter constant. *an* Cost per ton, $0.0116. *ao* Cost per ton, $0.0105. *ap* Compare with 8-ft. × 36-in. conical pebble mill at same plant, Table 77. *aq 98 J 564*. Compare 8-ft. × 18-in. conical pebble mill, Table 77. *ar* Compare 8-ft. × 20-in. conical pebble mill at same plant, Table 77. Against the slightly better grinding shown by the cylindrical mill, the conical mill requires 40 per cent. less floor space, has lower pebble and liner cost, and is less sensitive to inequality in feed rate. *as* The same screen tests are given at *20 CMI 98* as corresponding to 150 tons new feed per 24 hr. In the same article screen tests (*25*), Table 65*a*, are given as corresponding to 200 tons new feed per 24 hr. *at 16 Aa 126* Ore notoriously hard (*97 J 464*). *au* Ribs 4 in. wide, spaced 15 in. and when new stand 3¼ in. above plate, which is 1½ in. thick. *av* Fills mill to 2 in. above axis, which has been determined to be the best height. *aw* Pyramidal diaphragm boxes. See Sec. 6, Art. 5. *ax 123 P 88*. *ay* Wear on ends was more severe than on shell. *az* Tasmanian quartzite.

ba One mill 6 × 5-ft. and one 6 × 10-ft. in series. The first mill is in open circuit and discharges to a Dorr duplex classifier; the second is fed with the classifier sand and runs in closed circuit with the classifier. The first has since been changed to a ball mill lagged down to 5 ft. diameter. See Table 5. ***bb*** Removable side plates. White-iron digging lip, life 6 months. ***bc*** One-half silex and one-half rhyolite. ***bd*** Column 28, Table 65*a* gives feed and discharge of first mill and column 29 of second. Classifier overflow contains 0.4 per cent. +60-mesh and 83.3 per cent. −200-mesh. ***be*** Screen tests of a run at 30 tons per 24 hr. with diaphragm removed are given in Column 30, Table 65*a*. ***bf*** 8 in. below discharge level. ***bg*** *98 J 469*. ***bh*** See Table 73. ***bi*** Classifier overflow is 0.2 per cent. +150-mesh, 96.4 per cent. −200-mesh. ***bj*** Later reduced to 16 r.p.m. without change in capacity or grinding but with reduction of 33 per cent. in power. ***bl*** *48 A 16*. ***bm*** 6 × 6-in. inside. ***bn*** Flint and hard run-of-mine. Charge carried 2 to 3 in. above axis. Consumption 1.8 lb. of flint plus 2.0 lb. of hard ore per ton of feed. ***bo*** The mill in parallel with this discharged, at the time of sampling, a product containing considerably less coarse sand but 9 per cent. less −200-mesh. ***bp*** Classifier overflow, 1 per cent. +200-mesh. ***bq*** *60 A 103*. ***br*** Classifier overflow. ***bs*** *111 J 58*. ***bt*** Classifier overflow, 80 per cent. −200-mesh. ***bu*** Lumps of hard quartz, hard silicious rhyolite and scrap iron all failed to grind satisfactorily. Run-of-mine ore (soft calcite) wore too rapidly. River pebbles most satisfactory available material, but consumption was 110 lb. per ton and they cost $0.13 per ton ground. ***bv*** Shell about 8 mo. Pebbles will not wedge so all wear is taken on the iron. End-liners 4 months.

* Marks data from actual operations. Other figures generalized from makers' catalogs.

grinding the ultimate crystals of the rock-forming minerals, while much of the work of the ball mill lies in breaking the rock along the parting surfaces between the crystals. Resistance to such parting is much the same in many rocks, hence the resistance of such rocks to ball-mill grinding is similar. But the ultimate mineral crystals differ widely in hardness and toughness and there is consequent variable resistance to grinding in the tube mill. Accurate data on this score, which will form a basis for comparison between plants, are substantially impossible to collect and present, but the possible differences in grinding resistance must be borne in mind in estimating capacity, and final estimates in important cases should always await the test of actual trial.

Size of mill affects directly rather the size of feed that can be handled, size of product, and mill efficiency, than capacity, except that it is true that the larger mill has the larger capacity, from a given size of feed to a given product size, roughly in proportion to the comparative volumes. The diameter of the mill is one of the factors affecting the force of impact of the pebbles and also the superincumbent weight on the revolving pebbles in the grinding mass, hence it affects the work done by these forces. The length of the mill and feed rate determine the duration of the crushing action on any given volume of feed and for a given size of feed and product, length and feed rate vary directly. Table 67 arranged from Chalmers and Williams' catalog represents one school of thought as to the relation between diameter of mill and feed size. Brown (*104 P 206*) states that as a result of careful tests he has concluded that it is a waste of power to use larger than 4-ft. working diameter for −6-mesh feed; that small feed could be best crushed in smaller mills except for inconvenience in repairs; and that 5 ft. inside liners is big enough for −⅛-in. material. Gieser (*97 J 463*) summarizes the literature of American and foreign practice in cyanide plants and concludes that notwithstanding published results to the effect that the smaller-sized mills are the more efficient, especially on finer feeds, the majority of American mills are 5 × 18-ft. and the African mills 5½ × 22-ft., irrespective of the feed size. In the use of tube mills for preparing flotation feed, 6- and 7-ft. mills have been used for 10-mesh feed, on account of the shorter lengths used (10 to 12 ft.) and the high capacities demanded.

It is the common experience of all who have worked with tube mills that the bulk of the crushing is done in the head end of the mill and that, in a long mill, very little crushing is done in the last few feet. Fig. 27 shows this in an operating mill and Fig. 34 (*L. C. Pan, Columbia Univ., 1924*) shows the same thing in batch grinding. Table 68 shows that in a Rand tube mill, wet-grinding, crushing of coarse particles proceeds at a rapidly falling rate along the mill and that substantially 80 per cent. is completed in the first half. Production of −90-mesh is likewise performed at the greatest rate near the head end and 74 per cent. of the total sliming is done in the first half, but on the other

hand 20 per cent. of the total is done in the last 4 ft. The reason for the apparent inefficiency of the 12th to 17th foot inclusive is not apparent from the data. When, however, a mill is run open circuit, great length must be provided in order to crush the last of the oversize grains, and the finer the final product the greater the length that must be provided. Even for closed-circuit grinding, in which the classifier or other guard machine sends back the oversize, manufacturers recommend longer mills for finer products. Thus Chalmers and Williams recommend 6.5- to 14-ft. lengths for 20-mesh product; 9- to 18-ft. for 40-mesh; 12- to 20-ft. for 60-mesh; and 16- to 22-ft. for 100-mesh for closed-circuit work and 2 ft. above the maximum lengths recommended above for open-circuit work to the same sizes. Recent experience has shown that, if sufficient classifier capacity is provided to handle a large return tonnage, the shortest mills above listed are long enough for the respective sizes, and since power consumption is proportional to pebble load and hence to length, these are the most efficient.

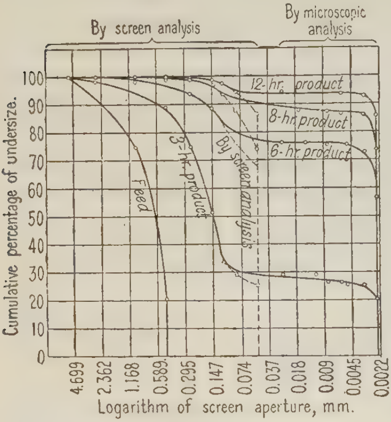

FIG. 34.—Effect of grinding time (length of mill) on product of a tube mill.

Robbins and Hanson (*109 J 194*) report a test at HOLLINGER in which 6 × 15-ft. tire-and-trunnion mills with 42-in. discharge opening were run on ⅛-in. disk-crusher product in competition with 5 × 20-ft. mills. All mills choked at normal tonnages. When feed was prepared in a ball mill, pebble and power consumption and general maintenance were all higher per ton ground in the 6-ft. mills. The writers attribute this reversal of recent South African experience to the fact that Hollinger ore is soft and friable while the Rand ore is hard and tough and to the fact that an all-slime product was sought while South African practice is to make a 60-mesh product.

Size of feed. Within limits, the amount of fine material produced per mill per unit of time increases with the size of feed. This general trend is shown in Table 69. Table 73 apparently emphasizes this fact but the fine feed there was a sand-table middling containing the hardest fraction of the original feed.

Nevertheless, by no means the whole difference is due to the mineralogical character.

Table 69. Performance of $5\frac{1}{2} \times 22$-ft. tube mills on Rand ore, using 6- to 9-in. cubes of banket for grinding medium

In 1910 the duty of Rand tube mills (*71 A 983*) treating stamp product through 15- to 25-(linear) mesh screens was not more than 80 tons of −90-mesh product per 24 hr. In 1919 a duty of 125 to 135 tons of −90-mesh was good current practice, the feed being stamp product through 0.75-in. screens. Total load, including circulating, with this duty was about 400 tons. This later practice involved the discharge and return to the stamp-mill bins of rejected rounded pebbles passing 1-in. circular holes and amounting to 0.5 to 2 per cent. of the total mill feed. Gieser (*97 J 466*) cites a South African mill that was divided for experimental purposes into two sections, one with 60 @ 1500-lb. stamps and 4 tube mills crushing about 16 tons per stamp per day through 0.3-in. and finishing to 65 or 75 per cent. −90-mesh in the 4 tubes; the other with 160 @ 1500-lb. stamps and 4 tubes, crushing 6 tons pe r stamp per day through 30-mesh and finishing in tubes. There was very little difference in the size of the final product in the two sections. The latest practice is the New State Areas plant (*113 J 1038*) in which ore is crushed by jaw and disk crushers to −1-in. and then sent to $6\frac{1}{2} \times 20$-ft. tube mills, driven by 250-hp. motors. Feed rate is 120 to 130 tons per day. Davis, Willey and Ewing experimented with yet coarser feeds and found that by increasing the circulating load, increasing the size and number of apertures in the discharge screen and making a reject-pebble discharge of about 25 tons per mill per day, the duty was increased to 130 to 140 tons of −90-mesh product with $-1\frac{1}{2}$-in. feed. By further raising the feed size to $-1\frac{3}{4}$-in. and rejecting 15 to 20 per cent. of the total feed as coarse pebbles the duty rose to 145 to 150 tons of −90-mesh product and the product contained a high percentage of −200-mesh material. With yet coarser feed (12.6 per cent. on 2-in.), 1.75-in. slots in the discharge screen and screen oversize broken in a set of 36 × 16-in. rolls and returned to the mill, 135 tons of ore and 12.9 tons of pebble rock were fed to a 5 × 22-ft. mill daily and produced 144.32 tons −90-mesh, leaving 2.3 per cent. on 90-mesh. The product contained 62.5 per cent. −200-mesh which was 15 per cent. less than in subsequent products when the mill circuit was closed by a Dorr classifier instead of diaphragm cones. With slightly finer material (2.1 per cent. on 2-in.) the mill feed was 144.2 tons plus 14.2 tons of pebble rock; the product contained 0.2 per cent. on 60-mesh, 4.2 on 90-mesh and 60.4 per cent.−200-mesh, and the duty was 151.48 tons −90-mesh per 24 hr. Increased duty with coarser feeds is ascribed by the above workers to be due to the ease with which the corners are broken and rubbed off irregular pieces, thus readily producing fine material, and to the free rejection of small rounded lumps and their re-cracking to irregularly shaped pieces before re-introduction to the mill. This process,

started in regular operation at the SPRINGS MINES in June, 1923, produced during the first month an average of 147.4 tons −90-mesh material per 5½ × 22-ft. mill in a product containing 2.1 per cent. +90-mesh and 71.4 per cent. −200-mesh. The circuit was closed by a Dorr classifier. It is to be noted that the economic efficiency of this method is probably limited to operations in which ore is used as a grinding medium. Using flint pebbles the pebble consumption would be too high.

Burt and Caetani (*37 A 3*) found that efficiency increased with coarseness of sand fed to the mill, up to 25-mesh. In the coarser range, at the old GOLDFIELD CONSOLIDATED mill in which everything was ground to pass 200-mesh, the most efficient work was done by stage grinding, from 1.5-in. to 4-mesh in 1050-lb. stamps, thence to 16-mesh in Chilean mills, and finishing in 5 × 22-ft. tube mills. (*102 P 616*.)

Size of product. Capacity and grinding efficiency both decrease with decrease in the size of product. Davis, *et al.*, found in working through a relatively narrow size range of product that the percentage increase in total tonnage ground was about twice the percentage decrease in amount of −200-mesh material in the product. Table 65 shows 0.040 ton per hp.-hr. grinding to 100-mesh and finer, 0.073 ton to 48- to 65-mesh and 0.179 ton to 10- to 20-mesh.

Weight of charge. The normal charge is close to 50 per cent. of mill volume. A somewhat greater charge is usually carried in the quick-discharge mills. Smaller charges are carried when the daily tonnage is less than the full mill capacity or when motor capacity is deficient.

Table 70 (*21 IMM 3*) gives the results of three tests with different charges in a 2.83 × 3.5-ft. laboratory mill operated open-circuit. These indicate equal grinding efficiencies

Table 70. Effect of weight of pebble load on performance of tube mill. (*After Ball*)

All tests at 12.6 tons per 24 hr. feed rate, 41 r.p.m. and 38 per cent. moisture.

with ⅜- and ½-loads with falling off at ⅝-load. The ⅝-load produces, however, the greatest tonnage of −200-mesh material. The decrease in grinding efficiency is due to an increase in power consumption which is entirely disproportionate and does not accord with Young's data (*58 A 126*) for the ball mill (p. 402) and is probably wrong, in which case Ball's maximum efficiency would correspond to greatest load. Fox (*28 M&M 537*) working with a 5 × 23-ft. mill, found that power consumption increased with weight of pebble load up to 23,000 lb. or 68.5 per cent. of mill volume and that the best load, on the basis of

tons of desired size produced per horsepower-hour was 18,000 lb. or 53 per cent. of the mill volume. Further increase in pebble load did not increase grinding. Graham (*16 JCM 57*) (see Table 64) shows that a light load of pebbles grinds slightly more per horsepower-hour than a heavy load, but that the heavier load grinds slightly finer at a given rate and size of feed.

An incidental advantage of the high charge is the fact that it insures automatic discharge of small pebbles that, as indicated by their discharge, are more or less floating in the pulp and doing no useful work.

Size of pebbles depends upon the size of the largest particles in the feed. The reasoning as to proper size of balls in ball mills (p. 339) applies here, but it is even more important to reject undersize pebbles than balls on account of their smaller specific weight and their consequent greater loss in grinding effect in a dense pulp with decrease in size. The consensus is that the charge should contain a mixture of sizes, the largest depending on the size of feed.

Chalmers and Williams recommend 2- to 3-in. maximum pebble size for 1/16-in. feed 3- to 4-in. for 1/8-in. feed, 4- to 5-in. for 3/16-in. feed, 5- to 6-in. for 1/4-in. feed and 6-in. for 3/8-in. feed, but the largest sizes are difficult to obtain. Brown (*104 P 206*) says that 2- to 3-in. pebbles are large enough for −6-mesh feed while for coarse feed (−1/3-in.) 5-in. pebbles should be used.

When pieces of mine rock or inferior pebbles are used they should be as large as possible (up to 7- or 8-in. lumps); the chances of obtaining pebbles of crushing size when they break will be greater, they will have a longer crushing life with consequent smaller dilution of the ore, and the consumption (and consequent cost) per ton will be less.

Speed depends primarily on the diameter of the mill. The best speed for a given diameter, according to White (*5 JCM 290*), is given by the equation $N = 215/\sqrt{d}$ where N = r.p.m. and d = internal diameter of the lining in inches. If d is taken as the nominal diameter of the mill in inches the formula agrees fairly well with American practice until recently. Present practice in the best-run mills is much below these figures, especially for fine grinding.

At Nipissing, grinding to 96 to 99 per cent. −200-mesh, the speed of 5 × 20-ft. mills with smooth liners was decreased from 26 to 21 and then to 16 r.p.m. with a total saving as between 26 and 16 r.p.m. of 33 per cent. in power consumption when handling identical tonnages to identical sizes. Speed should be slightly greater with relatively coarse feed and products than with fine since in coarse grinding maximum cascading of pebbles is desired. According to Brown (*105 J 246*) speed should be greater for thick pulp than for thin. Table 71 (*21 IMM 3*) indicates a distinct maximum efficiency in a 2.83 × 3.5-ft. laboratory mill at between 33 and 41 r.p.m., apparently nearer the lower figure, but substantially all of the difference is due to the power minimum at 37 r.p.m. and the accuracy of this measurement may be questioned.

Leupold (*Pro. So. Af. Ass'n Eng'rs, Apr., 1905*) states that at too low or too high speeds liner and pebble wear were excessive and the pebbles became flattened disks unsuitable for crushing.

Liner. (See also p. 426.) For fine feeds and very fine grinding smooth liners give highest capacity.

Careful tests at Nipissing where the endeavor was to make a final product with not over 2 per cent. +200-mesh, showed that highest capacity on −4-mesh feed was obtained with smooth iron lining and 60 per cent. moisture.

For somewhat coarser product a liner of the El Oro type gives greater capacity and the maintenance cost is less. With coarser feed or for relatively high tonnage a lining with lifter bars is essential for the best work. Of these the Komata is probably the most used and the most economical.

Open *vs.* closed-circuit grinding. The principles involved are the same as those discussed under ball milling (p. 391). The kind of device used to close the circuit is of great importance in determining capacity and size of product of a given mill.

Tons −200-mesh produced per horsepower-hour	0.013		0.014		0.010		0.011	

Feed rate, all tests, 7.2 tons per 24 hr.; 1200 lb. pebbles; 38 per cent. moisture.

Davis, *et al.*, found that while the capacity of a 5½ × 22-ft. mill grinding to 1 or 2 per cent. on 90-mesh was the same whether the circuit was closed by diaphragm cones or a Dorr classifier, the classifier overflow, representing the final product of the grinding, contained about 15 per cent. more −200-mesh when the Dorr classifier was used. Ball's work (*21 IMM 3*) on open-circuit grinding in a laboratory mill (2.83 × 3.5-ft.) is given in Table 72. From these data it would appear that grinding efficiency, measured in tons of desired

size produced per horsepower-hour, increased to a broad maximum somewhere between 14.4 and 23 tons per 24 hr. for that mill. The appearance of a maximum at 18.6 tons is clearly due to a corresponding minimum in the power curve. Fox (*28 M&M 537*) found that (within limits) power decreased with increase in feed rate and Mishler (*98 J 469*) that change in feed rate from 22 to 85 tons per 24 hr. did not affect power consumption. In the light of these data Ball's power measurements are not sufficiently convincing to justify the acceptance of this particular minimum. It is probable that there is considerable latitude in the allowable feed rate to a tube mill operated in open circuit, through which the tonnage of a desired fine size produced per unit of power remains substantially constant. This conclusion from Ball's data is confirmed by Table 73 which shows a maximum somewhere between 80 and 693 tons of fine feed per 24 hr. The product is progressively coarser as the feed rate increases and the choice of rate depends, therefore, on the character of product wanted. Burt and Caetani (*37 A 3*) found that efficiency increased proportionately to feed rate in open-circuit grinding and that in closed-circuit work it was higher with a large than with a small circulating load. Table 73, representing the results of work at the LUCKY TIGER mill (*98 J 469*) shows a continuing increase in tons ground in closed circuit per unit of power, with an increasingly coarse product, as the total tonnage of a 5 × 14-ft. mill was increased from 22 to 85 per 24 hr. on coarse feed and from 67 to 693 tons on fine feed. At the highest tonnage, although very little grinding was apparently done, judged from screen analysis of feed and product, yet greater tonnages of −100- and −200-mesh material were produced than with the apparently better grinding at the 67-ton rate. When, following these experiments, the original feed to the tube mills was increased from 26 to 50 tons per day per mill, the final classifier overflow remained unchanged at 80 per cent. −200-mesh and the power consumption per ton of initial feed ground was halved, becoming 22 hp.-hr. per ton. Costs of grinding, classifying, concentrating and circulating decreased from $1.88 with light feed (26 tons per 24 hr.) to $0.97 at 41 tons and $0.68 at 50 tons.

Tonnage of circulating load increases rapidly as tonnage of original feed increases, if the product size is held constant.

In Table 73, with 37 tons of original fine feed per 24 hr., the total load was 216 per cent. of the original feed; with 50 tons original feed, 478 per cent; and with 75 tons, 925 per cent. According to Mishler, when the total load at LUCKY TIGER exceeded 400 per cent. of the original feed the cost of elevating and concentrating the circulating material exceeded the saving due to greater mill capacity. When sands are not treated and the classifier acts as an elevator, the most economical total load may easily exceed this figure. Easton (*13 CME 89*) found that the capacity to a given size was greatly increased by closed circuit and furthermore, what has been frequently observed by other operators but is rarely mentioned in the literature, that the capacity of the circuit is frequently determined by the classifier rather than the mill. Using a 6 × 20-ft. quick-discharge mill grinding from −6-mesh to about 8 per cent. + 100-mesh and 70 per cent. −200-mesh for flotation, when the feed rate was 144 tons per 24 hr. there was practically no sand return while an increase in feed rate resulted in sand return, so that 144 tons may be taken as the maximum open-circuit capacity of the mill. With the same classifier, the overflow when the mill was fed 240 tons per 24 hr. contained 15 per cent. + 100-mesh and 56 per cent. −200-mesh, but with a larger classifier the overflow at 240 tons was the same size as at 144 tons. Easton found also that the power draft decreased with increase in tonnage passing through the mill. Thus at 144 tons per day original feed, 40 per cent. moisture and, as above noted, but little sand return, the power draft was 75 kw.; at 180 tons and 38 per cent. moisture, the draft was 70 kw.; at 240 tons and 38 per cent. moisture, 65 kw. and at 350 tons and 40 per cent.

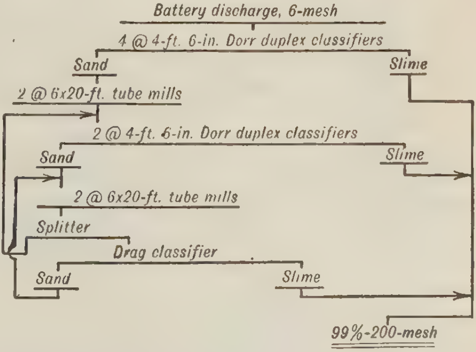

FIG. 35.—Flow-sheet of 2-stage tube milling and classification at Nipissing. (Bowl classifiers later substituted.)

moisture, 55 kw. Thus with increased grinding and decreased power consumption accompanying increase in feed rate, there is marked increase in efficiency and decrease in cost. At NIPISSING (*48 A 16*) six 4-ft. 6-in. duplex Dorr classifiers and one drag classifier were used with four 6 × 20-ft. tube mills in grinding from 6-mesh to 1 per cent. + 200-mesh. The flow-sheet is shown in Fig. 35.

Moisture. The percentage of moisture in the mill feed should be from 30 to 50. This is slightly greater than is best for coarse ball-mill feed, owing to the fact that with the finer material a given percentage of moisture gives thicker pulp and consequently more water must be used to maintain the proper pulp consistency.

Table 74 (*21 IMM 3*) shows an apparent maximum grinding efficiency with fine feed at 38 per cent. moisture, but the change in the range from 30 to 58 per cent. moisture is not

great. Smart (*10 JCM 443, 11 JCM 15*) found that the best moisture content varied with the total tons of solid passing through the mill and that 27 per cent. was best with 200 tons per 24 hr. while 39 per cent. was best with 400 tons per 24 hr. Fox (*28 M&M 537*), working with a 5 × 23-ft. silex-lined mill on − 12-mesh feed found that with 39.6 per cent. moisture and grinding to 50 per cent. through 150-mesh the mill took 55 hp. while with 54.6 per cent. moisture, grinding to substantially the same product, 62.3 hp. was consumed. Sherrod (*Mex. IMM, Dec., 1909*) found a maximum capacity between 40 and 45 per cent. moisture with a very fine (7 per cent. +60-mesh) feed.

Ball's figures apparently show that the percentage of fines in the mill discharge decreases with increase in moisture content. This is probably the usual experience but in the copper mills of LAKE SUPERIOR high moisture is used to get fine product and similar experience elsewhere is far from unusual. When the tube mill is of the overflow type, increase in moisture should yield a finer product by analogy with the Dorr classifier, while in a quick-discharge mill high moisture content should cause coarse discharge.

Power consumption depends upon weight of pebble load, diameter of mill, speed, type of lining, and consistency of pulp. For estimates, an average figure of 6 to 7 hp. per ton of pebble load for a 5-ft. center-discharge mill with silex lining, loaded to the axis and grinding a pulp containing 35 to 40

per cent. water, is safe, if an additional allowance of 50 per cent. is made to cover starting overload. For a smaller load in the same mill the power per ton is greater on account of the increased moment arm. Scoop-discharge mills require 25 to 30 per cent. more power. Smooth metal liner will require 5 to 10 per cent. less power, El Oro-type about 5 per cent. more and ribbed liners from 10 to 20 per cent. more. James (*21 IMM 3*) gives 7 hp. per ton of pebbles for Rand mills ($5\frac{1}{2} \times 22$-ft.) with silex lining. The power requirement under like conditions for mills of other diameters can be obtained from the equation $Hp. = 1.5\ DT$ where D = nominal diameter in ft. and T = tons of pebble load. The power requirement for mills of given diameter and loading varies roughly in proportion to the speed, within the limits of speeds ordinarily employed. A thin pulp requires more power than a thick because it allows the relatively dense pebbles to crowd further away from the axis of revolution. Merton (*38 MEW 1129*) recommends as best that speed at which $Hp./r.p.m.$ is a maximum.

Operation. Feed rate, size of feed, and moisture content should be kept constant, the pebble load must be kept up to weight and worn and cracked pebbles rejected from the circuit, if the mill is to operate efficiently. Close classifier regulation is essential as it affects both the allowable feed rate and the product size. The mill should be opened for inspection at sufficiently frequent intervals to insure that the liner does not become dangerously thin, and, in the case of ribbed liners, that the ribs have not worn down so much that their lifting effect is lost. Discharge grates should be kept open. An ammeter is a great aid to steady operation; any decided variation from the normal reading indicating abnormal work of the mill. A high reading ordinarily indicates an increase in moisture content, or, in the case of a surcharged mill, a deficiency of pebbles. With an undercharged mill a high reading indicates more than the normal pebble load or an increase in feed rate. Lubrication must, of course, be regularly attended to. Lack of lubricant will show first on the ammeter reading. Grease is used on trunnion bearings and gears and oil on the pinion shaft. Consumption of grease averages about 1 lb. per shift, oil less than ¼ pint.

Cost of tube milling should average between \$0.08 and \$0.12 per ton in grinding to table size; \$0.15 to \$0.25 to flotation size and \$0.25 to \$0.40 to 150- or 200-mesh. Individual costs may depart considerably from these figures due to local conditions.

At WAIHI, N. Z. (*16 Aa 126*) (see Table 65) the average cost to 60-mesh including labor, supplies, power and overhead in 1912 was \$0.1766 per ton. RAND cost in 1914 grinding to a few per cent. on 60-mesh was about \$0.12 per ton. (*97 J 467.*) At CHURCHILL MILLING Co. (*52 A 129*) the cost (1914) of grinding hard, tough quartz ore, closed-circuit, in a 5 × 22-ft. tube mill from 20-mesh to 95 per cent. − 100-mesh was: labor, \$0.029; supplies, \$0.119; power, \$0.107; total, \$0.255. At BARNES KING DEVELOPMENT Co. (*60 A 104*) the cost per ton ground from − 20-mesh to 1 per cent. on 65-mesh (1917) was: labor, \$0.0500; supplies, \$0.1223; power, \$0.0702; total, \$0.2425. At GOLDFIELD CONSOLIDATED (*89 J 1230* [1910]) the cost per ton ground from − ¼-in. to 200-mesh was \$0.202. At NIPISSING (*31 Ont. Dep. Mines 259*) the average cost for the years 1913 to 1922 incl. for two-stage reduction from − 4-mesh to − 200-mesh, including classification, was: labor, \$0.13; supplies, \$0.22; power, \$0.32; shops, \$0.05; total, \$0.73 per ton. At COBALT REDUCTION Co. (*ibid.*), grinding from − 3-mesh to − 40-mesh (1922) the cost per ton was: operating labor, \$0.023; repair labor, \$0.012; balls, \$0.144; liners, \$0.092; power, \$0.122; total, \$0.393.

Tube mill *vs.* grinding pan. Table 75 shows the result of a competitive test at Homestake (*22 IMM 93*). The tonnage of fine material produced by the pan per hp.-hr. is more than that produced by the tube mill when fed at the regular rate but the tube mill is so superior in low consumption of grinding medium, in capacity per unit, and in water consumption (permitting mate-

rial reduction in dewatering equipment) that its advantages far outweigh its larger power consumption per unit weight crushed.

15. Conical pebble mill

Description. The conical pebble mill is similar in construction to the conical ball mill except that it is lighter and usually differently lined. The shell is made of steel plate with butt joints and double-riveted butt straps. Heavy cast-iron flanges are riveted at the end and carefully faced for attachment of the cast-iron trunnions. The usual sizes with weights, power required and capacity, according to the manufacturer's catalog, are given in Table 76.

Table 76. Specifications for conical pebble mills. (*Hardinge Co. catalog*)

P = Product.

NOTES TO TABLE 77

a Italic numbers refer to column numbers in Table 77*a*. *b* One man for 6 rolls, 3 pebble mills and 2 drag classifiers. *c* Worn liners from ball mills. *d* Added daily at a rate, determined by consumption, to keep load at a constant average. *e* Added as needed to keep ammeter reading constant. *g* Feed, 87 per cent. +48-mesh; product, 22 per cent. +48-mesh. *h* Ends, silex; cylinder, El Oro, cast iron. *i* One mill has manganoid lining with lifting bars of the Komata type, life 245 days, consumption, 0.722 lb. per ton; re-lining takes 6 men 99 hours: the other, manganese-steel lining without lifting bars, life, 256 days, consumption, 0.46 lb. per ton; re-lining takes 6 men 55 hr. *j* Local hard ore. Costs about $2 per ton extra to pick out but contributes to concentrate and would have to be milled anyway. Saving in pebble cost is $0.15 per ton (*104 J 71*). *k* Hourly according to operator's judgment of grinding. *l Questionnaire and Salt Lake Min. Rev., Nov. 15, 1918.* *m* Classifier overflow contains 1 per cent. on 28-mesh and 34 per cent. −200-mesh. *n* Ribbed in cylinder, smooth in cones. *o* Local quartzite. *p* Average cost (1918), $0.0141 per ton. *q* Classifier overflow is 2 per cent. on 35-mesh and 35 per cent. −150-mesh. *r* Compare with preceding column and also with conical ball mill at the same plant, Table 11. *s* Cost per ton, $0.0062. *t* Cost per ton, $0.0155. *u* Compare with 6 × 9-ft. tube mill at the same plant, Table 65. *v 98 J 564.* Compare tube mill at the same plant, Table 65. *w* Compare 5 × 18-ft. tube mill at the same plant, Table 65. *x* Compare 8-ft. × 22-in. ball mill at Miami, Table 11. *y 13 CME 897.* *z* In closed circuit with trommel and cone. Screen analysis of discharge is of actual discharge and not of final product of closed circuit. *aa* Pebbles set in cement. *ab* Crude ore. *ac* No. 2 mill in the same plant, running at 23 r.p.m. took 65 hp. and crushed a slightly coarser feed slightly finer at the same feed rate. *ad* Silex blocks, 8 months; pebbles set on end in cement, 4 months; local cut blocks, 2 months; Komata and Britannia also used but life not available. *ae* Local pebbles. *af* Average of 22-in., 30-in., 36-in. and 48-in. mills. *ag* Heated and quenched in water before crushing. *ah* Feed end elevated 4 in. to obtain granular product. *ai* Colbath classifier. *aj* Combination of ribbed cast iron and pebbles set in cement. *ak 20 IMM 44.* *al 119 P 808.* *am* Classifier overflow contains 0.6 per cent. +65-mesh and 56 per cent. −200-mesh. *an* Feed end elevated 6½ in. *ao* El Oro and ribbed plate, alternating. *ap* 8-ft. × 72-in. pebble mills at Tamarack plant take 100-hp. motors and have about three-times the capacity of these mills (*117 J 282*). See also 8-ft. × 72-in mill at Calumet and Hecla, this table. *aq* 64 mills set in two rows are all served by a 15-ton crane that can pick up a full mill, carry it to a re-lining floor, dump the load into a spare mill standing there, set the old mill on a standard and set the spare into place on the operating floor, all in one hour. Two extra mills are sufficient for the entire plant (*117 J 282*). *ar* Open circuit necessary because native copper builds up and slimes excessively in closed circuit (*117 J 282*). *as 101 J 316.* *CI* Cast iron. *DC* Dorr classifier. *DF* Danish flints. *Mn* Manganese steel. *O* Oil. *SS* Spiral scoop, one-way. *WB* Wedge bar.

At Inspiration a 10-ft. × 28-in. mill drawing 90 hp. ground 190 tons per day of feed containing 43.7 per cent. on 8-mesh and 26.7 per cent. −48-mesh to 2.3 per cent. on 48-mesh.

Capacity is dependent upon the same factors as in tube mills. (See p. 437 for discussion.) Table 78 gives capacity figures from manufacturer's catalog and from actual practice. These figures are reasonably safe for estimate with average ores. Most of the figures from practice are for open-circuit work and could be exceeded somewhat in closed circuit.

Shape of mill. Increasing the length of the cylindrical section increases capacity, power consumption and fineness of grinding.

At Miami (*115 P 568*) a 6-ft. × 38-in. mill re-ground as much as two 6-ft. × 22-in. mills. At the same plant an 8-ft. × 66-in. mill re-ground 294 tons per 24 hr. from 10- to 28-mesh for 74 hp. while an 8-ft. × 22-in. mill ground 178 tons from 3- to 10-mesh for 47 hp. (see Tables 85 and 86). The longer mill had the harder material to grind. At Calumet and Hecla an 8-ft. × 72-in. mill ground 2½ to 3 times as much as an 8-ft. × 18-in. mill but drew three times as much power. It is probable that about 48 in. is the maximum economical length of cylindrical section for 8-ft. mills and smaller, that fineness should be attained by closing the circuit and capacity by installation of another mill, probably best arranged for stage reduction.

Power consumption ranges from 5 to 7 hp. per ton of pebble load for 6-ft. mills and from 6 to 12 hp. for 8-ft. mills, the higher figures in both cases corresponding to a long cylindrical section and an under-charge of pebbles. Tons crushed per horsepower-hour averages about 0.15 to table size (10- to

20-mesh), 0.10 to a coarse flotation size (28- to 35-mesh) and 0.050 to 100-mesh.

* From Table 77.

Field of conical pebble mill in ore milling is fairly restricted at present. When first put on the market as a competitor of tube mills and roller mills in grinding for concentration the conical pebble mill was superior and supplanted them. As a slime producer, however, it has never been able to compete successfully with the tube mill except on very soft ores. As a grinder for table or flotation concentration it has been generally superseded by ball or rod mills on account of their greater capacity. Only under certain special circumstances, *e.g.*, in re-grinding very hard ores such as Lake Superior copper conglomerate, where the consumption of balls and metal liners is excessive, or where granular nature of the product is more important than cost of grinding, is the conical pebble mill now the best machine.

16. Conical pebble mill *vs.* other grinders

Conical pebble mill *vs.* Chilean mill. Results of an exhaustive test at Miami Copper Co. are presented by Franke (*47 A 50*). The product desired was sand below 60-mesh for gravity concentration. The conical mill yielded 47 per cent. of such material against 36.2 per cent. from the Chilean and yet did not produce quite so much − 200-mesh slime, which was very difficult to treat. The conical mill was smoother running, required less attendance, used less water and consequently required less de-sliming equipment. Results of the competition are shown in Table 79. A similar situation developed at Moctezuma Copper Co. before the introduction of flotation. The feed to the mills assayed 1.8 per cent. copper and the best size range for gravity concentration was from 20- to 200-mesh. An 8-ft. pebble mill ground 71.5 tons per 24 hr. to 1.8 per cent. on 20-mesh. A 6-ft. Chilean mill ground 83.5 tons to 33 per cent. on 20-mesh. The pebble mill product contained 54.8 tons of the desired product containing 71.8 per cent. of the total copper against 30.3 tons containing but 34.3 per cent. of the total copper from the Chilean. Detailed results are given in Table 80. Results of competitive work in producing flotation feed at Braden (*29 IMM 204*) are

shown in Table 81. The Huntington mill was clearly outclassed by both the Chilean and the conical mill and the performance of the conical mill was better than that of the Chilean,

even if an allowance is made to the Chilean for its coarser feed. As a matter of fact, the conical mill would have done substantially the same work on the Chilean-mill feed as it did on the feed provided it.

a At $36–$39 per hp.-yr. *F* = Feed. *P* = Product.

Conical pebble mills *vs.* tube mills. Comparing the two mills on the basis of tons crushed per horsepower-hour from the data in Tables 65 and 77, the tube mill grinds more (0.179 against 0.150 ton) open-circuit to table sizes; substantially the same, allowing for differences in the particular sizing tests, to flotation size; and somewhat less (0.040 against 0.050 ton) to cyanide sizes. But the available data on the conical mill in sliming are too few to support the apparent conclusion of superiority in cyanide grinding, and this fact in itself is a strong argument against that conclusion, indicating, as it does, the inability of the conical pebble mill to make a place for itself in this service against the tube mill in the fifteen years that it has contended.

At Anaconda (*59 A 245*) a 10-ft. × 48-in. pebble mill was tested against an 8 × 12-ft. tube mill grinding −2-mm. sand tailing to 48-mesh in closed circuit with Dorr classifiers. The conical mill crushed 163 tons per 24 hr. with a power consumption of 15.9 hp.-hr. per ton and pebble consumption (Danish flints) of 7.2 lb. per ton. The tube mill crushed 177 tons per 24 hr., consumed 17.7 hp.-hr. per ton and 14.0 lb. of Danish and French pebbles. Wiggin says that they considered the mills on a par as to efficiency and cost.

Pebble mills *vs.* ball and rod mills. The use of balls as grinding media instead of pebbles permits a greater weight of charge in the same mill volume, a greater number of crushing units of the same size, each with greater striking force, and a greater area of crushing surface. As a result, the capacity of a given mill is greatly increased by such substitution and the product when grinding to table or flotation size is usually finer. On the other hand, power consumption is increased rather more than in proportion to the increased weight of charge, liner wear is increased, the cost of grinding medium per pound is usually greater, while consumption per ton ground is the same or

greater. Table 82, summarized from Tables 4, 5, 11, 50, 65 and 77, indicates the rod mill superior in point of power consumption to both ball and pebble mills in producing table and coarse flotation feed (with the limitation as to size of mill feed discussed in Art. 12). Pebble mills, on the other hand, are superior or equal to ball mills in power economy in the same range, subject, however, to a similar limitation in feed size. Table 83 shows equal power con-

sumption as between balls and pebbles per ton ground but finer product from coarser feed and greater capacity for the ball mill. Ball and ball-mill liner wear in this case cost at least 4 times as much as pebble and pebble-mill liner consumption.

At COPPER RANGE an 8-ft. × 30-in. mill carrying 10,000 lb. of pebbles ground 65 tons per 24 hr. Change to 9000 lb. of balls raised the capacity to 150 tons without substantial change in screen test of product. At MIAMI COPPER CO. change in load of an 8-ft. × 22-in. conical mill from 8000 lb. of pebbles to 15,000 lb. of balls, open-circuit grinding, increased capacity from 178 to 300 tons per 24 hr. and produced a slightly finer product at a slightly lower rate per horsepower-hour. Pebble consumption was 1.14 lb. per ton and consumption of 2-in. manganoid balls 1.21 lb. per ton (see Table 84.) Closing the circuit on the ball

mill with a Dorr classifier gave a yet finer product at substantially the same power consumption. Comparative costs are given in Table 85. Power for ball milling cost 8.2 per cent. more than for pebble-mill grinding; grinding medium, 251 per cent. more and lining 152 per cent. more; labor cost was about the same for both. At the same plant, changing the grinding load in an 8-ft. × 66-in. conical mill from pebbles to balls increased average capacity from 250 to 330 tons per 24 hr. but doubled the per-ton power consumption and more than doubled the cost per ton for re-grinding (see Tables 86 and 87). On the other hand, the product re-ground in the ball mill contained 97.6 per cent. −65-mesh material while that from the pebble mill contained only 48.2 per cent. and was unsuitable for flotation feed. Further, the capacity of a mill section with a ball re-grinding mill was 822 tons per 24 hr. against 714 tons with a pebble mill. Increased recovery and tonnage on the ball-mill

section more than compensated for increased re-grinding costs. CALUMET AND HECLA is the only large plant in this country that has continued to use pebble mills in re-grinding for concentration. Their stand is clearly justified by Benedict's statement (*117 J 282*) that on the hard conglomerate ore pebble wear is 4 to 5 lb. per ton and ball wear almost as great; pebbles cost $0.0075 per lb. and balls $0.035 per lb.; and the difference in cost on this score alone is $0.10 per ton in favor of pebbles. At WRIGHT-HARGREAVES (*115 J 884*) there was an actual saving in power attendant upon a change from pebbles to balls. Two 5 × 16-ft. cylindrical pebble mills with El Oro liners ground ball-mill product to 60 per cent. −200-mesh at the rate of 125 to 150 tons per 24 hr. and consumed 70 to 75 hp. (= 0.045 to 0.050 tons −200-mesh per hp.-hr.) Change to ball loads (20,000 lb. each mill) increased the daily

capacity to 200 to 260 tons containing 80 to 85 per cent. −200-mesh and power consumption at 28 r.p.m. was 90 to 100 hp. (= 0.078 to 0.087 ton −200-mesh per hp.-hr.)

17. Chilean mill

The Chilean mill developed from the ancient arrastre (Art. 20). The first step was a single stone roller running on a stone pavement. The modern counterpart of this step is the slow-speed mill. In the years 1900 to 1910 the high-speed form, representing the highest development, had considerable vogue in gravity-concentrating mills, but ball and pebble mills have now almost completely superseded it in concentrating practice. Slow-speed mills have been put forth by a few engineers as a one-step machine from rock breakers to amalgamating table in competition with stamps alone or stamps plus tube mills, but they have been adopted only in a few small plants or in backward countries where substantially fool-proof operation is essential. Repairs are frequent and slow to make and the parts are heavy and difficult of access. Lennox *(63 A 521)* states the now generally accepted conclusion, *viz.*: that the Chilean mill is not a fine grinder and hence not a true competitor of ball and pebble mills.

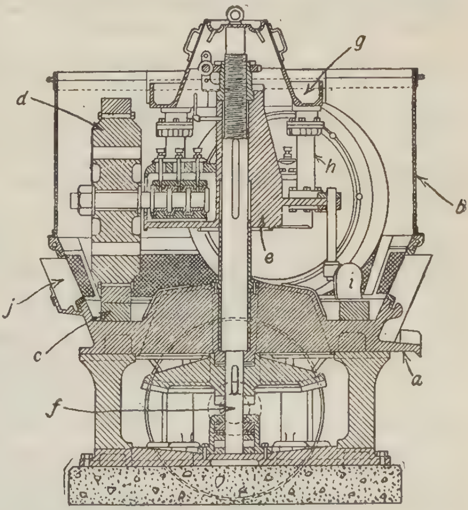

FIG. 36.—High-speed Chilean mill.

High-speed mill. A typical high-speed mill is shown in Fig. 36. The essential parts are a circular cast-iron pan (*a*) with screen and sheet-iron wall (*b*), a die ring (*c*) and three steel-shod circular rollers (*d*). The method of mounting and driving the rollers differs in different makes. In the figure, the rollers are rigidly mounted on axles carrying thrust bearings trunnion-

mounted in an adjustable yoke (*e*) driven by feathers from spindle (*f*). The vertical position of the yoke on the spindle is adjustable by means of nuts on the threaded upper portion. This permits lowering the axles as the tires and die wear and also, by inclining the axles downward toward the spindle, utilizes, in crushing, a certain proportion of the centrifugal force developed. The feed stream, introduced into the annular box (*g*) is led by pipes (*h*) to a point just ahead of the advancing rollers. Scrapers (*i*), following the rollers, churn up the material on the dies and help to keep the fines in suspension. Travel of the rollers causes a circular swash of pulp against the screen through which ground material discharges into the annular launder (*j*) and is led away. Each roller is free to lift independently when an uncrushable lump is encountered. In another form the thrust bearings are rigid in the yoke and the latter is carried on a spherical bearing on the spindle. The whole table tilts when one roller passes over a large particle. Both types of mill are made, infrequently, with overdrive and also with fixed axles and the journals in the roller hubs. Over-drive is clumsy and less rigid than under-drive. Hub journals are difficult to lubricate and protect against grit.

Sizes. High-speed mills are made in sizes from 2- to 8-ft. diameter, weighing 6000 to 125,000 lb. respectively. The commoner sizes are the 5- and 6-ft. weighing respectively about 30,000 and 50,000 lb.

Low-speed mill. The modern form of low-speed mill has two to four rollers running on a die ring 6- to 10-ft. diameter. The rollers are made very heavy, or, in one form (LANE MILL) are on axles whose bearings are attached rigidly to the yoke while the latter carries a large tank that may be loaded with several tons of ore or pig iron in order to add to the crushing load. The SIZE OF PRODUCT is determined by the height of the overflow lip and moisture content, no screen being used.

Mantey offset. In some slow-speed mills the center line of the roller shaft is offset slightly behind the center line of the spindle. This accentuates slipping of the roller face on the die surface and increases abrasive action.

Drive. Mills should be fitted with an oversize clutch on account of the great inertia of the heavy revolving parts and the consequent heavy power draft at starting.

Performance of high-speed mills in American concentrating practice is given in Table 88.

At the GAIKA PLANT (*20 IMM 161*), Rhodesia, a 5-ft. Akron (high-speed) mill with 30-mesh screen was run at 43 r.p.m. The feed was all through 1.5-in., trommel and battery screen, 10.4 per cent. on 1.25-in.; product, 1.5 to 3.5 per cent. on 40-mesh, 38 to 49 per cent. − 150-mesh according to whether the dies were new or worn (new dies did finer crushing but at lower capacity). Power consumed, 25 hp.; consumption of chrome-steel tires and die, 0.646 lb. per ton, aver. life 53 days. At GREAT GOLD BELT mine, Amboy, Calif., (*92 J 305*) a Lane 4-roller slow-speed mill with 7-ft. (O.D.) die-ring, running at 10 r.p.m. with 4-in. discharge height, crushed − 1-in. feed (hard, close-grained quartz-hematite) at the rate of 20 tons per 24 hr. to substantially 40-mesh, with 86 per cent. through 100-mesh The weight tank contained 4½ tons of rock. The size of product was determined entirely by height of discharge and moisture content. Inside amalgamation was practiced. This mill was installed to answer the demand for a low-cost unit of small capacity and low water and power consumption. At the SANTA ELENA plant, Guanajuato, Mex. (*90 J 967*) a slow-speed mill with Mantey offset crushed 27 tons per 24 hr. of − 2-in. average quartz ore through 40-mesh wire screen. The product contained 1 per cent. on 60-mesh and 67 per cent. − 200-mesh. Speed was 15 r.p.m.; moisture 89 to 91 per cent.; horsepower, 15 (0.075 ton per hp.-hr.). Ton-cap screen of the same aperture gave notably higher capacity than square-mesh. Dies and tires lasted 18 mo. COST was $0.235 per ton, of which power was 62 per cent. and tires and dies 28 per cent. At HACIENDA DE LA UNION (*86 J 989*) a slow-speed 2-roller mill with overflow discharge 23 in. high ground quartz ore from − 1¼-in. to 0.4 per cent. + 80-mesh and 80 per cent. − 200-mesh at the rate of 15 tons per 24 hr.

The wheels were 8-ft. diam., 16-in. face, weighed about 8 tons and were mounted with Mantey offset. The die ring was about 4-ft. diameter. Speed was 10 r.p.m.; power consumption, 10 hp. Cost was about $0.35 per ton. Bayldon (*20 IMM 125*) describes 7- to 10½-ft. 2-runner slow-speed mills used in Russia for crushing and amalgamating relatively soft gold ores. Taking – 3- or 4-in. breaker product, these mills crushed from 16 to 26 tons per 24 hr. through 0.5- to 1-mm. screens with a consumption of 7 to 12 hp. Speed was 11 to 14 r.p.m. The product contained less than 1 per cent. on 30-mesh and 63 to 88 per cent. – 200-mesh. Tons per horsepower-hour ranged from 0.065 to 0.095. Steel consumption averaged 1.2 lb. per ton. In an improved type of mill (8-ft. 6-in. mean diameter of die ring) with 2 runners weighing 5 tons each and making 14 to 16 r.p.m., 3-in. crusher product was ground to 30-mesh (70 to 80 per cent. – 200-mesh) at a rate of 40 tons per mill per 24 hr. or about 0.1 ton per hp.-hr. Weight of mill was 23 tons. At La Union (*93 J 393*) a Pachuca-type mill ground from 1½-in. to 80 per cent. – 200-mesh at one pass at the rate of 0.071 ton per hp.-hr.

The low-speed mill is a competitor of the modern high-speed mill and of stamps plus tube mills. Compared with the former (see Table 88), the tons per horsepower-hour to 30-mesh is low, but the feed is much coarser than any sent to the high-speed mills. Bayldon states that the capacity of one of his mills was increased 63 per cent. by a speed increase of 14 per cent. while the power increase was less than 62 per cent. Maintenance charges are, however, greatly increased by increase in speed and the fool-proof character is largely lost. Stamps plus tube mills crush through the same range at the rate of about 0.05 ton per horsepower-hour. On this basis alone the Chilean mill is superior, but except in small plants, the number of units required is so great and lost time so large that labor and maintenance charges outweigh the apparent power saving.

Speed of mill affects size of product, capacity and power consumption. High speed makes coarser products and consumes more power, if the feed rate is the same. If the product is held to the same screen test the mill with higher speed has the greater capacity. Thus at the Portland plant (*63 A 523*) a 6-ft. mill at 37 r.p.m. ground 282 tons coarse feed per 24 hr. through 6-mesh screen (see Table 89). The same mill at 29 r.p.m., grinding to an almost identical screen analysis, handled 186 tons per 24 hr. only and consumed 93 hp.

Size of feed. Capacity through a given screen is considerably greater with feed of 0.75- to 1.5-in. maximum size than with, say, 3-mesh feed, (*33 CMJ 832*) the apparent explanation being that the coarse particles break up the swirl and cause sand to be deposited on the tire for grinding. At Portland comparative tests on 2-in. and 10-mesh feeds with 18-mesh screen on the mill (Table 90) showed more tons produced per horsepower-hour at every screen size with coarse than with fine feed, the discrepancy growing less the finer the screen taken. It was found impossible to raise the power draft with fine feed to more than 80 per cent. of that with coarse feed.

Size of product is determined by the screen aperture, height of screen above die ring, speed, moisture content, and whether the mill is operated in closed- or open-circuit. Finer screens produce, of course, finer products (see Table 89), but both tons per machine and tons per horsepower-hour are less with fine screens. On the other hand, the amounts of the finer sizes produced per horsepower-hour may increase with decrease in screen size, *e.g.*, the tons of – 20-mesh product is greater in Table 89 with 18-mesh screen than with 6-mesh screen. The tonnage of the finest sizes (65- to 200-mesh) per horsepower-hour is not greatly affected by change in mill screen. For the finest grinding, slow-speed mills without screens but with high discharge and relatively high moisture content are used. Running in closed-circuit with a classifier makes finer product with a given screen than open-circuit grinding (see Table 91).

Open *vs.* closed-circuit. Table 91 shows the results of comparative tests at the Portland mill. Closed-circuit and open-circuit work produce substantially equal tonnages of – 28-mesh material per horsepower-hour but closed-circuit work produces more – 200-mesh. Further tests with 6-mesh screens on the mill showed that with an original feed of 251 tons and sand return of 217 tons per 24 hr. (46.3 per cent.) the number of tons per horsepower-hour of coarse feed (see Table 90) ground was 0.089, tons – 65-mesh product per horsepower-hour was 0.058 and tons – 200-mesh, 0.035. With 198 tons original feed and 310 tons return (61.0 per cent.) the corresponding tonnages were 0.078, 0.056 and 0.035. This shows economy in the smaller return.

Moisture. Increase in moisture increases capacity but causes discharge of a coarser product. Comparative tests at Portland mill are shown in Table 92. Tons −65-mesh and −200-mesh, product per horsepower-hour are substantially the same with the two moistures tested. The higher moisture with corresponding higher tonnage is indicated as the better practice, if the coarser product is satisfactory metallurgically or if the following re-grinding machines reduce sands as cheaply as the Chilean mill. Lennox' conclusion from mill operation was that 75 per cent. moisture is best; usual practice, according to Table 88, lies between 60 and 75 per cent.

a For feed analysis, see Coarse feed, Table 90.

Power consumption with a given feed increases with the feed rate, all other things remaining constant. Lennox found that with a feed rate of 256 tons per 24 hr. and power draft of 114.2 hp. the tons −20-mesh product per horsepower-hour was 0.083 and the −200-mesh, 0.028 (Table 90). Reducing the power draft to 84.1 hp., by reducing the feed rate to 171 tons reduced the production of −20-mesh material to 0.075 ton per hp.-hr. while −200-mesh, remained the same. With softer ores, tons per horsepower-hour through 6-mesh screens averages about 0.2. At Miami (*115 P 568*) two 6-ft. Chilean mills handled 480 tons per 24 hr. with 150 hp. By increasing the feed rate to 550 to 600 tons, power increased to 175 hp. or over and the product was markedly coarser.

Wear of tires and dies when crushing relatively soft copper ores from 6- or 10-mesh to 14- to 20-mesh in high-speed mills averages about 0.25 lb. per ton. On hard conglomerate ore the consumption is 1 lb. Ferguson (*50 A 298*) gives a consumption of 1.06 lb. per ton on very hard silicious ore in Montana and 0.24 to 0.30 lb. on softer ores in Colorado and Mexico. These figures represent the usual extremes.

Cost. At Churchill Milling Co. (see Table 88) cost (1914) was: labor, \$0.026; supplies, \$0.053; power, \$0.063; total, \$0.142 per ton. At Barnes-King Development Co. (see Table 88) cost (1917) was: labor, \$0.1253; supplies, \$0.0689; power, at \$0.07 per kw.hr., \$0.0617; total, \$0.2559. At Portland (*63 A 531*) cost per ton (1918) was; labor, \$0.0231; supplies, \$0.0975; power, \$0.0764; total, \$0.1970.

Chilean mills *vs.* Huntington mills *vs.* rolls. At Nevada Consolidated mill (*123 P 325*) comparison was possible between 6-ft. Chilean mills, 6-ft.

Huntington mills and 35 × 16-in. rolls set close, all re-grinding −3⁄16-in. table tailing. Comparative performances are shown in Table 93. The results indicate the Chilean mill the best and the Huntington poorest in production of −30-mesh material (table feed) per horsepower-hour although the Huntington-mill product was the more granular (least −200-mesh material produced per ton of feed or per ton of −30-mesh produced). Repairs were highest on the Huntington mills. Only one roll was driven, which, in part, explains the high slime production.

Slow-speed mills *vs.* stamps, stamps and tubes, etc. McLaren (*101 J 15*) presents a strong argument for the slow-speed mill. In comparing it to stamps he cites two western U. S. mills working on medium-hard quartz ores.

Tons −65-mesh produced per horsepower-hour	0.048		0.039	
Tons −200-mesh produced per horsepower-hour	0.027		0.025	

The first mill used ten 1440-lb. stamps and one 5 × 16-ft. tube mill. Feed was 80 tons −2-in. material per 24 hr.; battery screens were No. 12 Ton-cap, and battery product contained 25 per cent. −200-mesh, which was removed ahead of the tube mill. Stamps drew 34 hp. and the tube mill 40 hp., so that the tons per horsepower-hour was 0.098 for the stamps and 0.045 for stamps plus tubes. In the other plant three 10-ft. Lane mills drawing about 12 hp. each crushed 48 to 50 tons each per 24 hr. from −2-in. to 40 per cent. −200-mesh with discharge height of 6½ in. Tons per horsepower-hour was 0.167 to 0.174, or about 70 per cent. more than that for the stamp battery, and the product contained 60 per cent. more −200-mesh, which would take 20 per cent. of the load off the tube mill in the first plant. McLaren also compares a 10-ft. Lane mill at 8 r.p.m. crushing 40 tons per

24 hr. of −1.5-in. feed to 53 per cent. −200-mesh and drawing 12 hp. (0.139 ton per hp.-hr.) with the first two steps in the 3-stage reduction at GOLDFIELD CONSOLIDATED where 1050-lb. stamps crushing −1.5-in. feed through 4-mesh screen were followed by high-speed Chilean mills with 16-mesh screens and these by 5 × 22-ft. tube mills. Stamp duty was 8.5 tons per 24 hr. for 2.4 hp. (0.148 ton per hp.-hr.) and the product contained 20 per cent. −200-mesh; Chilean mills handled 75 tons per 24 hr. for 35 hp. (0.089 ton per hp.-hr.) to 30 per cent. −200-mesh. Tube mills ground 95 tons per 24 hr. to 95 per cent. −200-mesh and drew 60 hp. (0.066 ton per hp.-hr.) Taking the first two stages as a unit, 0.056 ton were ground per horsepower-hour to 44 per cent. −200-mesh, which is substantially half that of the slow-speed mill. At BONITA MILL, Barron, Wash. (*85 J 1053*) a 5-stamp battery with 25-mesh screens ran side-by-side with a 5-stamp battery with 4-mesh (No. 16-wire) screen and a 10-ft. Lane mill in series. Discharge height in the mill was 6 in.; speed, 6 r.p.m.; power consumed, 12 hp. Stamps alone crushed 16 tons per 24 hr. and the product contained 10 per cent. on 30-mesh and 14 per cent. −100-mesh. Stamps plus Chilean mill crushed 40 tons per 24 hr.; product contained 4 per cent. on 30-mesh and 36 per cent. −100-mesh. Extraction on plates and tables was much better on the finer pulp.

Chilean mills *vs.* conical pebble mills. See Art. 16.

Chilean mills *vs.* Huntington mills. See Art. 16.

18. Huntington mill

Construction. Huntington mill (Fig. 37) consists of a cylindrical cast-iron tub (*a*), 3½ to 6 ft. diameter, with screened openings (*b*) in the walls to permit controlled egress of ground pulp; a die ring (*c*) wedged in place against the wall near the bottom; and four rollers (*d*) suspended like governor arms from the yoke (*e*) which is keyed onto the upper end of the driving spindle (*f*). As (*f*) is revolved through bevel gearing from driving pulley (*g*), the rollers (MULLERS) are pressed against the die ring by centrifugal force and roll around, crushing material between them and the dies. Feed is introduced with water at hopper (*h*), the swirl set up by the revolving mullers throws it against the dies to be crushed and against the screens for discharge. The principal wearing parts are the roller tires, ring dies and screens. Tires and dies are usually made of chrome steel. Screens are woven wire or punched plate.

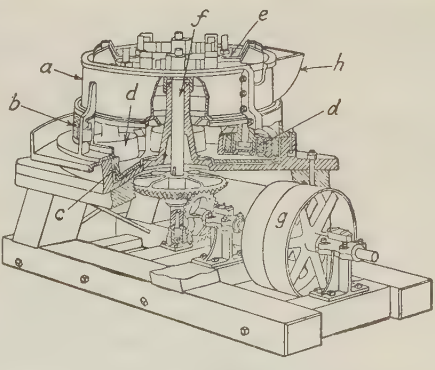

FIG. 37.—Huntington mill.

At ANACONDA, crushing de-slimed 10-mesh middling to 20-mesh, a 6-ft. mill with punched-slot screen crushed 74 tons per 24 hr. against 58 tons with woven wire. Average life of the punched plate was 12.4 days and of the wire screen, 13.3 days.

Weight ranges from 7000 lb. for 3½-ft. mill to 50,000 lb. for the heavy 6-ft. mill.

Operation. Mills are usually run at a peripheral SPEED of 1000 ft. per min., based on the nominal die-ring diameter but Semple (*42 A 602*) reports that increase in speed of a 5-ft. mill from 70 r.p.m. to 90 increased capacity from 50 to 75 tons per 24 hr. Low MOISTURE CONTENT makes for fine grinding and low steel consumption but reduces capacity greatly; the usual practice is 75 to 85 per cent. moisture, which supplies sufficient water to wash material through the screens readily. The die ring and mullers both wear unevenly and this causes excessive pounding and rapid destruction of the mill. Metal shoes made to replace a muller are used to grind down the die ring and muller shells should be removed and turned down when the faces get flat. Average STEEL CONSUMPTION is from 0.75 to 1.5 lb. per ton of feed. POWER CONSUMPTION varies from 5 hp. for 3½-ft. mills to 25 for a heavy 6-ft. mill with heavy feed. FEED should be fine (0.25-in. or under) unless the ore is very soft. Coarse feed causes excessive bumping because the crushing force is insufficient to break large lumps and the muller is forced to pass over them and then flies back against the die. CAPACITY to 20-mesh ranges from about 8 tons per 24 hr. for a 3½-ft. mill with coarse (−0.75-in.) feed to as high as 185 tons in a heavy 6-ft. machine re-grinding soft table middling from 10- to 20-mesh (see Table 94). The product is granular and well suited to table concentration. This is one of the principal ADVANTAGES of the machine. Another is the fact that it is especially adapted to sectionalizing for mule-back transport and can therefore be used in inaccessible regions. The DISADVANTAGES are the close attendance required and high repair and maintenance charges. The Chilean mill was an almost universally successful competitor before the advent of ball and tube mills, which latter have driven both mills out of the field. COST at TONOPAH MINING CO. (*91 J 1213*) grinding through 0.02-in. rectangular mesh was $0.52 per ton, of which $0.21 was for repairs.

Punched-plate screen, 14-mesh. Feed rate, 74 tons per 24 hr.

19. Grinding pan

Construction. The grinding pan (Fig. 38) consists essentially of a cast-iron tub, usually about 5 ft. diam. and 2½ to 3 ft. deep, carrying a broad annular die ring on the bottom, on which heavy shoes are dragged by means of a yoke; this in turn, is driven by a spindle from bevel gears and a belt-driven counter-shaft below the pan bottom. Shoes and dies are ordinarily of gray cast iron which wears down with a rough scored surface. White iron and alloy steels are unsuitable because the wearing faces become smooth and polished with accompanying reduction in capacity.

At GREAT FINGALL, Australia (*11 CME 291*) shoes and dies corrugated circumferentially had higher capacity than plane shoes and dies, metal consumption was lower (2.9 to 3.0 lb. per ton against 3.6 to 3.8) and power consumption was less on account of the lower speed.

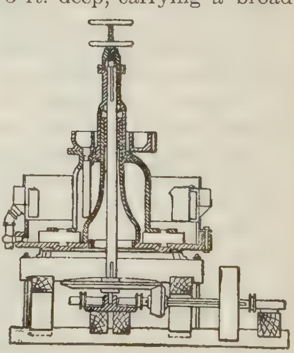

FIG. 38.—Grinding pan.

An adjusting screw with locking wheel is provided for adjustment of the height of shoes. Mullers, which carry the shoes, should be attached to the

yoke arms by a flexible fitting in the nature of a universal joint; if a rigid joint like that in an amalgamating or clean-up pan is used, the shoes will often chatter, capacity be reduced and breakage increased. Die ring and shoe circle are sometimes continuous, but ordinarily short spaces are left both between the shoes and the die segments. These form channels into which pulp flows and from which the crushing faces are fed. New shoes weigh 75 to 200 lb. and the crushing force is limited to that exerted by this weight when dragged over the die. Compensating weights are sometimes used to keep the crushing force up to normal as the shoes wear.

Pans are of two general types, *viz.:* ordinary and positive. In the ordinary pan the feed is introduced at any point, although preferably this is near the center, and discharge is by peripheral overflow or its equivalent. Fineness of product is controlled by height of discharge. Baffles are placed on the inner wall of the pan to return pulp to the center. Capacity is low and power consumption relatively high on account of the large body of pulp that is kept in motion. The POSITIVE PAN is fed through a central cylinder discharging near the bottom of the pan at the inner edge of the die ring. Pulp flows outward through the shoe and die channels and is then forced upward along the walls of the pan by centrifugal force induced by the swirling action. Discharge is low. Size of product is controlled by outside classification (or screening) or by a screen (COBBE-MIDDLETON), or a classifier (FORWOOD-DOWN) attached to the pan walls.

Performance. At PERSEVERANCE mine, Kalgoorlie (*16 MM 300*) 8-ft. Wheeler pans (ordinary type) 3½ ft. deep, with a small spitzkasten on the outside of the pan wall fed near the top by a row of ¾-in. holes and having a slot 3 × 2-in. at the apex to return sand, were used. The speed of different pans varied from 25 to 30 r.p.m. A higher speed could be used with slime-free feed. Capacity was 40 to 45 tons per pan per 24 hr.; power draft, 7 hp. each; tons per horsepower-hour, 0.24 to 0.27. Feed contained 50 per cent. +150-mesh and product 30 per cent. Amalgamation was practiced in the pans. Shoes and dies were gray cast iron, 2½ in. thick; life of shoes, 3 mo.; dies, 6 to 9 mo., each being worn to about 1-in. thickness; consumption, 0.35 lb. per ton ground. At HOMESTAKE (*22 IMM 93*) modified Wheeler pans, 5-ft. diameter, with peripheral overflow adjustable as to height were used to re-grind and amalgamate. Feed was received in a cup forming part of the muller carriage and delivered by pipes directly in the path of the shoes. Total revolving weight was 2200 lb.; power draft, 8.4 hp. at 58 r.p.m. Capacity was about 20 tons per 24 hr. or 0.099 ton per hp.-hr. Screen tests of feed and product are given in Table 95. At BECK MINING CO., Wyo. (*108 P 417*) a 5-ft. ordinary pan at 68 r.p.m. in closed circuit with a Dorr classifier ground 26 tons per 24 hr. from 10-mesh to 80-mesh. (Table 95.) Pulp in the pan contained only 30 per cent. moisture when operating best. At KYLOE, N. S. W. (*22 IMM 16*) 8-ft. Forwood-Down pans at 30 r.p.m. with classifying discharge were used to grind jig tailing to flotation feed. (Table 95.) The product contained too much +40-mesh material. Raising the overflow increased the percentage of slime produced but did not greatly affect the amount of +40-mesh. Finally the classifier discharge was removed and the machines were put in closed circuit with King screens, which solved oversize troubles. At BROKEN HILL (*100 J 152*) 8-ft. Forwood-Down pans at 32 r.p.m. ground 2 to 2½ tons per hr. from −3-mm. to 10 per cent. +40-mesh; 5-ft. pans of the same type at 50 r.p.m. ground 1½ tons per hr. through the same range with a consumption of 8 hp. (0.187 ton per hp.-hr.). Cast-iron shoes and dies lasted 6 to 8 weeks, equivalent to 2.5 to 3 lb. wear per ton ground. Stage crushing was found preferable to single-step and tube mills much cheaper than pans. At the ZINC CORPORATION (*118 P 90*) −7-mesh +20-mesh jig tailing was ground to flotation size (40-mesh) in 5-ft. pans at the rate of 1.25 tons per hr., return sand bringing the total up to 3 tons. These pans were originally installed as non-sliming fine grinders for gravity concentration and were not as good as tube mills for flotation feed. At PRESTEA BLOCK A, West Africa (*106 J 54; 22 JCM 149*) 5-ft. Cobbe-Middleton pans, having a weight-and-lever device for holding the shoes against the dies, were used for grinding and amalgamating pyritic concentrate. The duty on −10-mesh feed with 14-mesh screen was 8.2 tons per 24 hr. of −60-mesh product or 5.7 tons −90-mesh. This was at the rate of 0.048 ton −90-mesh per hp.-hr. and is comparable to 0.052 ton −90-mesh per hp.-hr. in Rand tube mills on similar ore. (See Table 95.) Wear of shoes and dies including waste, which was large, was 0.9 lb. per ton ground. The pan had maximum capacity with new shoes and dies.

F = feed. *P* = product. *D* = pan discharge. *CO* = classifier overflow.

Positive *vs.* ordinary pan. Söhnlein (*96 J 581*) reports comparative performances of positive and ordinary types. At a Bolivian tin mine, 5-ft. pans of the ordinary type run at 32 r.p.m. ground 2.5 tons per 24 hr. as shown in Table 95. At 60 r.p.m. practically no grinding occurred in a pulp containing 20 per cent. solid. Variation in discharge height from 2 to 3 ft. made no appreciable difference in character of product (at 32 r.p.m.) and the lower height was adopted because of lower power consumption. By changing the feed from a launder discharging near the center of the pan to an annular cup with pipes leading down to the inside of the shoe circle, the speed could be increased to 40 r.p.m. and capacity was raised to 7 tons per 24 hr. (See Table 95.) Feed and product were both coarser than in the unmodified pan but the tonnage of fines produced by the modified pan is much greater. At 50 r.p.m. (see Table 95) the discharge was too coarse. Further change to a positive pan with central feed cylinder, 20-in. overflow height and outside classification (Dorr) with return of oversize increased capacity to 38 tons per 24 hr. at 60 r.p.m. (See Table 95.) Consumption of cast-iron shoes and dies was 0.67 lb. per ton in the positive pan. Cost was \$0.09 for metal, \$0.19 for power (at \$0.0375 per hp. hr.), labor and lubrication, \$0.02; total, \$0.30.

Pan *vs.* tube mill. See Art. 14.

20. Arrastre

The arrastre is a primitive machine much used in early Mexican gold-milling for grinding from −1-in. size to slime. Practice in building varied, but the usual form was a circular pit, walled with rock or logs and chinked with clay, the bottom lined with flat stones similarly chinked, over which flat-

bottomed cubical stones weighing 100 to 1000 lb. were dragged by means of a horse-drawn sweep. Ground pulp overflowed through pipes at about 6 in. above the floor. Amalgamation was commonly practiced in the machine. CAPACITY varies from 200 or 300 lb. per day of soft ore in machines 3 or 4 ft. in diameter to 2 to 5 tons in 8- to 12-ft. mills.

Storms (*91 J 1053*) gives the following details of construction of the double arrastre shown in Fig. 39. Floor (*a*) was a double layer of 2-in. plank. Walls (*b*) were built of circular segments of 2-in. plank nailed together. The bottom of the basin was filled with a layer of firmly-rammed clay, then 6 to 8 in. of sand in which the floor blocks of hard, tough stone were laid. The edges of the blocks were left rough so that the spaces between them would afford settling places for amalgam. The floor sloped about one in 8 toward the sluice gate, which was 6 in. wide, extended 4 in. below the top of the rock floor and was closed by a sliding door. The discharge height was varied by 1-in. strips laid in cleats. Drags weighed 800 to 1000 lb. Massive diabase, diorite or granite served well for both floors and drags. The drags were fastened to chains by ⅝-in. eye-bolts wedged into holes 5 in. deep, and were set to sweep pulp into the path of the following stone. The front end of the drag stone should be lifted about 1 in. in order to nip large particles. The water wheel was of the hurdy-gurdy type; pipe line 7-in. diameter with 2-in. nozzle; water available, 18 cu. ft. per min. under 100 ft. head. Pinions were 3-ft. diameter with 13 hardwood pins 2-in. diameter, 4 in. high and 4 in. center-to-center. The horizontal pin wheels of 2-in. plank spiked and bound with strap iron were 6-ft. diameter with 51 pins similarly shaped and spaced. The main shaft revolved on 3-in. iron gudgeons. The bearing for the center post was made of 4-in. square steel 7 to 8 in. long with a spherical depression 3-in. diameter by 1½ in. deep, smoothly finished, tempered at bronze color and set in the upper end of the lower post, which was bound with an iron collar to prevent splitting. The gudgeon in the foot of the revolving post was forged to fit.

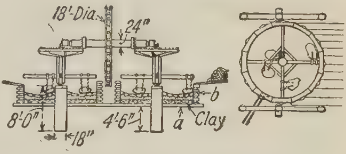

FIG. 39.—Arrastre.

Operation. When amalgamating in this machine batch operation was practiced. Ore was charged a little at a time with enough water to make a thin mud (40 to 60 per cent.) and ground for 5 to 7 hr., or until fine enough to add mercury, after which addition grinding was continued 2 or 3 hr. or until panning showed all free gold amalgamated. The speed of drags during amalgation should not exceed 360 ft. per min.; higher speed could be used during crushing, but repairs were less when the desired capacity was attained with heavy drags and low speed. During the latter part of the amalgamation period the drags were slowed down to 150 ft. per min. and pulp diluted to allow coarse grains to settle and be ground and amalgam to settle in cracks. When panning showed the pulp free of amalgam, the basin was raked and sluiced out gently and the floor cleaned up in the usual manner (see Sec. 8, Art. 11).

21. Swing-hammer pulverizer

The swing-hammer pulverizer (Fig. 40) is probably the most widely used of the crushers that depend upon impact to break 2- or 4-in. lumps to ½- or ¼-in. size. The essential parts are a plurality of disks (*a*) mounted on a rapidly-revolving shaft, each disk carrying a plurality of hinged beater arms (*b*). This mechanism is enclosed in a cylindrical chamber (*c*) lined with heavy breaking plates (*d*) and a grid or cage (*e*). Feed entering hopper (*f*) is struck by the beater arms and thrown against the breaking plates and against the cage until broken fine enough to fall through the cage openings. The cage and toothed breaker

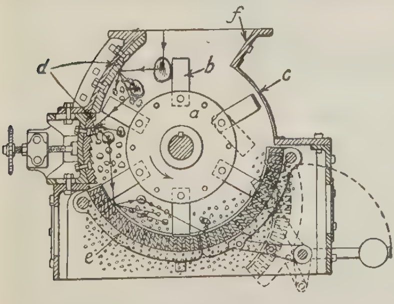

FIG. 40.—Swing-hammer pulverizer.

plates are adjustable as to distance from the central shaft, which permits take-up to compensate for wear and adjustment for size of discharge. Hammers, liners and grids are made of high-carbon tool or manganese steel. The machine is made in many SIZES and is used for crushing many different materials, mostly in the industrial field. A few of the sizes with data from actual operations are given in Table 96. Some hammer machines take 5- to 6-in. feed but the usual practice is to feed them with 1- to 3-in. material.

Table 96. Swing-hammer pulverizers. (*From Jeffrey Mfg. Co. catalog*)

Size, diameter × length, inches	Weight, pounds	Speed, revolutions per minute	Approximate horsepower	Grid spacing, inches	Capacity		
					Material	Tons per hour	Size product
18 × 9	....	....	6	1	Dolomite	0.33	50% − 20-m.
24 × 18	2,700	1200–1500	20	1	Dolomite	5.5	50% − 20-m.
30 × 24	4,700	1000–1200	35	0.06	Sea coal	3	75% − 40-m.
36 × 18	5,800	1000	45	0.25	Limestone	8	60% − 20-m.
36 × 24	6,400	1000	60	0.06	Limestone	9	80% − 24-m.
36 × 30	7,600	1000	80	0.06	Limestone	10	50% − 60-m.
36 × 30	7,600	1000	80	0.125	Limestone	18	90% − 20-m.
36 × 30	7,600	1000	80	1	Limestone	25	− 0.25-in.
36 × 30	7,600	1000	80	1	Culm	50	− 0.25-in.
36 × 30	7,450	1000	80	1	Bit. coal	50	− 0.25-in.
42 × 36	8,700	800–1000	100	1	Bit. coal	75	− 0.25-in.
42 × 48	17,000	800–1000	110	1	Bit. coal	100	− 0.25-in.
48 × 48	19,000	700–800	125	1	Bit. coal	125	− 0.25-in.
48 × 60	24,000	700–800	200	1	Bit. coal	180	− 0.25-in.

In the hammer-bar machine U-shaped bars take the place of the hammers. They are generally used for somewhat finer feed (0.5-in.) than the swing-hammer machines.

According to Williamson (*37 TAIEE 1550*) hammer mills (all types) crush 0.14 to 0.16 ton per hp.-hr. from 2½-in. maximum to 20-mesh.

CAPACITY is markedly affected by moisture. At one plant a machine that crushed 75 tons per hr. of bituminous coal through a ¾-in. screen when the coal contained 4 or 5 per cent. moisture would crush only 50 tons of coal containing 9 to 12 per cent. moisture. In asbestos work the discharge grid holds back coarse fiber and causes it to be over-crushed. Tramp iron causes serious breakdowns. A machine handling 15 to 20 tons per hr. of 3-in. rock draws 100 hp. (*123 P 934*). Lincoln (*Bul. 11 UI No. 9*) says that a No. 00 Williams pulverizer at 2200 r.p.m. reduced Illinois bituminous coal to ⅜-in. at the rate of 1.25 tons per hr.

Ring pulverizer is a variation of the swing hammer machine in which alternate hammers are replaced by heavy rings of such diameter that the diameter of the circle described by their outer faces is the same as that described by the beater tips.

22. Kent cracker

This machine (Fig. 41) consists of a pair of toothed rolls fitted above with a set of reciprocating steel picks in a cross-head crank-driven from one of the roll shafts. These picks both crack large particles and force them down to be nipped by the rolls. The machine is suitable only for cracking soft material that comes in lumps too large to be nipped by ordinary toothed rolls. It is used for breaking chalk at BENJAMIN MOORE Co., Carteret, N. J. (*116 J 415*).

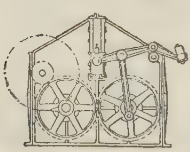

FIG. 41.—Kent cracker.

23. Jumbo mill

The Jumbo mill (Fig. 42) consists of a shaft carrying hinged beater arms and revolving at high speed (400 to 800 r.p.m.) in a closed cylinder. Feed is introduced at one end, material is carried forward by deflection of the arms and the product is discharged at the other end. In another mill of the same general type, the beater arms are more closely spaced and arms carried on the cylinder walls project between them. The cylinder is split in half longitudinally, the lower half hinged to swing down and allow easy access for repairs.

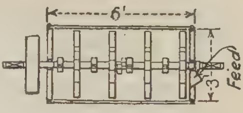

FIG. 42.—Jumbo mill.

24. Cyclone mill

This machine (Fig. 43) has two heavy (1000-lb.) 2- to 4-armed propeller-shaped beaters (*a*) revolving at high speed (2000 to 2200 r.p.m.) in a closed chamber. The direction of rotation of the two beaters may be the same or opposite; the latter gives the greater disintegrating effect. Feed enters on both sides at (*c*), directly over the beaters, and is discharged by suction from the top of the chamber.

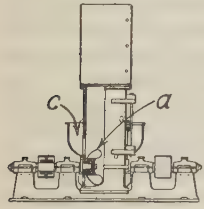

FIG. 43.—Cyclone mill.

The machine has been used in asbestos work, but on account of the great wear of propellers (lives as low as two days are recorded) has been generally replaced by other machines. FEED is – 1-in. size. CAPACITY ranges from 2.5 tons per hr. on hard asbestos rock to twice this figure on soft rock. In crushing soft rock from 2-in. to 0.25-in. the capacity may go up to 15 tons per hr. POWER DRAFT is 65 hp. Overfeeding causes material to accumulate on the bottom of the machine and be over-crushed. Tramp iron does great damage.

Torrey cyclone has a vertical ball-bearing shaft carrying two sets of vanes, one above the other, all suspended in a box-like chamber lined with manganese steel plates. The shaft is driven at 1000 to 2000 r.p.m. Material about 3-in. maximum size is fed onto a distributing plate at the top, falls onto the top impeller, is hurled against the liner plates, and broken. It then falls to the lower impeller, where it is further broken and then discharged. Tramp iron does not do much damage under ordinary circumstances. Hubbard (*123 P 934*) states that 17 hp. will run a machine handling 12 to 15 tons per hr. of asbestos rock.

25. Dry grinders

In addition to ball and tube mills, there are a number of mills of the ring-roller type used in this service, particularly in grinding coal and cement clinker. (See *37 TAIEE 1540*.) The FULLER MILL has heavy steel balls which are pushed around at high speed on the inner periphery of a circular die ring. In the coarse grinder, finished product is fanned out through a screen surrounding the upper part of the grinding chamber; in the fine grinder air classification is induced above the grinding chamber by connection with an external suction fan. The capacity with four or five 12- to 14-in. balls is 6 to 8 tons per hr. of coal or similar material from ½-in. to 95 per cent. – 100-mesh, drawing 35 to 60 hp. at speeds of 90 to 130 r.p.m. In the KENT MILL a vertical ring die revolves around 3 rollers that are held against it by powerful spring pressure. The crushing range is from – 1-in. to 20-mesh. Power consumption is about 1 hp.-hr. per barrel on cement clinker, 3 to 5 hp.-hr. per ton on cement rock. The BONNOT MILL is substantially a vertical-ring Huntington, 36-in. die ring, 75 hp. at 180 r.p.m., 4 to 5 tons per hr. from – ⅝-in. to 97 per cent. – 100-mesh. The GRIFFIN MILL resembles the Huntington in the placing of die and screens but has a single grinding roller with pendulum-like suspension. The RAYMOND MILL is similar to the Huntington but with an air-classifying attachment for raising finished material out of the grinding zone. CAPACITY, according to Williamson is about one ton per hr. per roll from ¼- or ½-in. feed to 95 per cent. – 100-mesh. Power consumption of a 2-roll mill is 45 to 50 hp.; 3-roll, 55 to 60 hp ; 4-roll, 75 to 80 hp.; 5-roll, 85 to 90 hp. None of these mills is used in concentrating practice.

26. Operation of crushing machinery

For maximum economy of power consumption machines must be kept up to full capacity without overloading. In closed-circuit work the return circuit should be carefully watched. Increase in tonnage of this circuit above normal will probably cause reduction in capacity. The usual causes of excessive circulating loads, depending on the flow-sheet, are: wear of crushing faces or a slacking off in their spacing, blinding of screens, reduction of rising current in hydraulic classifiers and, in the case of cylinder mills, change in moisture content of mill or classifier pulp. Steady feed is necessary for the most economical operation of all crushers; it is absolutely essential for cylinder mills; on the other hand the difficulty of attainment may excuse the lack in the case of coarse crushers. Liners and replaceable crushing surfaces should be replaced before they are worn through. Neglect causes an increasing diminution in crushing efficiency and, aggravated, may result in destruction of the machine structure itself, *e.g.*, the head, shell, or trunnion of ball or tube mills; the main frame of jaw or gyratory crushers or rolls, etc. Lubrication is of immense importance, both from the point of view of power consumption and that of bearing wear. Dry-crushing machinery working, necessarily, in a dusty atmosphere, should be provided with grit-proof bearings where possible and lubricated by a pressure system that forces lubricant out through any crevices through which grit might enter. Heavily-loaded bearings, such as those of cylinder mills, require a lubricant that cannot be squeezed out and the discharge bearing particularly must be protected against splash and the working back of pulp from the discharge bell. The usual expedients are a discharge bell of goodly length and wide flare, which reduces splash and increases the distance from splash to bearing, provision of one or more drip rings between the edge of the discharge bell and the bearing, and some kind of cloth fabric rubbing against the outside of the bell between the lip and the bearing to wipe off pulp. This wiper, however, rapidly becomes dirty and useless.

27. Crushing efficiency

Considerable work has been done in the attempt to find a means for determining the efficiency of crushing. True mechanical efficiency is not capable of determination because it is impossible, in the present state of knowledge, to measure the useful work done. Determination of relative efficiency is also highly elusive. One of the four methods described below is usually employed.

Cost comparison. This method consists in actual competitive tests of the machines that are to be compared, under operating conditions, keeping close records of tonnages crushed to the desired size, cost of operation, and, where advisable, of metallurgical results, from which records, by suitable comparison, the merits of the competing machines can be determined. Costs should include, in addition to power, operating labor, supplies, maintenance and supervision, charges for interest, depreciation and amortization. Such comparison as this is expensive and is justified only in the largest plants. Even in such plants the method is difficult and uncertain, since the test installation is rarely run on as large a scale as the finished plant and the test runs are rarely of sufficient duration to allow the most economical operation.

Tons crushed per horsepower-hour. This is the simplest of the purely physical methods of comparing crushing machines. It requires determination of the tonnage, power consumption, and screen analysis of the material produced. If the feed to competing machines is of the same character in all respects, and if the size of the product is unimportant except for the one requirement that it shall all pass a given limiting screen, and if maintenance and capital charges can be neglected, this method is satisfactory. But if the amounts of material in the different sizes below the limiting size are important, the method does not necessarily give a correct measure of the comparative performances of the crushers. It may be modified by calculating the average size of product from the screen analysis and stating performance in tons of a given average size produced per horsepower-hour, but in this case it is usually necessary to stipulate in addition that all material has passed the limiting screen, and the final figures that are reached are incapable of accurate comparison because of the fact that average size is not a definitely significant quantity (see Sec. 22, Art. 5) and that the average sizes of the products as estimated will probably be different. Thus if two competing crushers break a given feed through, say, a 1-mm. screen, and the first produces 5 tons per hp.-hr. of material having an average size of 0.5 mm., while the other produces 4.5 tons per hp.-hr. of material of 0.3-mm. average size, no conclusion as to relative efficiency of the crushers by this method is possible. If concentration showed that both products were equally amenable to treatment, a conclusion could be reached on the basis of costs. If the crushers that are being compared are not fitted to take the same size of feed or to make a product that will pass the same limiting screen, then, clearly, no such comparison as that described in this paragraph is possible.

Relative mechanical efficiency implies a rating for crushing machines similar to that employed for rating prime movers. Such rating involves the ratio of useful work done to energy expended. Unfortunately, as has been stated above, it is impossible to determine the amount of work usefully expended in crushing. Work expended in overcoming friction and inertia of the machine parts, in rubbing between particles and between particles and crushing surfaces, in producing deformation without breaking, and in making noise and generating electricity in the crusher is not useful, as the word is used in discussion of efficiency. An indication of useful work can, however, be reached by measuring the reduction in size of particles in the crushing operation and attributing thereto, in arbitrary units, certain energy values. When this is done, a statement of relative efficiency can be made as follows: $E = WT/P$. Where E is the relative mechanical efficiency, W is the number of units of size reduction per unit weight of material crushed, T is the number of units of weight of material crushed per unit of time, and P is the number of units of power used.

Opinion is divided as to the method to be employed in assessing the equivalence of useful work and size reduction. Two methods have been proposed. These are named respectively Kick and Rittinger from their proponents.

Kick's law states: "The energy required for producing analogous changes of configuration of geometrically similar bodies of equal technological state varies as the volumes or weights of these bodies." Stadler (*19 IMM 471*) has worked out a method of applying this law to rock crushing and has developed ORDINAL NUMBERS, corresponding to different sizes of crushed material, that, accepting the law, are proportional to the amount of useful work done

to produce the given size from a certain unit size. Stadler's reasoning is summarized in the following quotations from his article.

"The area of fracture over which the cohesion of the molecules has to be destroyed, multiplied by a coefficient determining the resistance which the molecules oppose to their separation by the exercise of any stress (crushing, tensile, shearing, etc.) represents the *force* required to cause the fracture.

"In order to perform mechanical work, this force has to run through a *distance*, represented by the deformation which the body can stand before reaching the breaking point. It is in this connection immaterial that this distance of deformation within the limits of elasticity and plasticity is, for not perfectly homogeneous bodies, subject to variations, which for highly elastic and unplastic bodies as quartz, glass, etc., are too insignificant to be considered, and in addition they are, by the nature of our crushing appliances averaged to such an extent, that these averages are as good as exactly defined figures. Dealing with relative values only, we have not even to care about the exact extent of this deformation, and all that we need is, to be satisfied that this factor is a constant function of the diameter of the particles to be crushed.

"The *mechanical work done* is represented by the product of the *force by the distance*, but as in a regular scale of reduction by volume the diameters of the particles decrease at the same ratio as the area of fracture increases, the product, or the mechanical work for reducing the volume (or weight) of the unit from one grade to the next following, *is a constant for each grade*, called the crushing or ENERGY UNIT (EU).

"The volumes of the particles decrease from grade to grade in the same ratio as the number of the particles, constituting in their total the volume of the unit[y] increases, and the product of the volumes into the number of the particles of that grade is, therefore, constant for each grade. As in conformity to the above law, the amount of energy absorbed is proportional to the volume of the body to be crushed, it follows again also that the total energy required for reducing the weight of the unit *is constant for each grade*.

"The ORDINAL NUMBERS of any arithmetical progression given to these grades represent consequently the relative values of the energy which has to be spent upon producing this respective grade from the initial unit, or the *mechanical value* of the grade.

"For obtaining the *mechanical value of mixed sands*, we need only to multiply the percentages of the gradings by the number of the energy units of the respective grade and add the products.

"The *useful work done per unit* by any crushing machine is determined by the difference between the mechanical values of the samples taken at the inlet and the discharge of the machine, and for obtaining the *total work done* this difference has to be multiplied by the tonnage dealt with."

Stadler's formulas for determining ordinal numbers and various other factors regarding crushed material are presented in Table 97 (*48 A 153*). If the screens used in making the sizing test vary in aperture from screen to screen by a constant multiplier, the ordinal numbers will be whole numbers in an arithmetical progression. Numerical values of the quantities in Table 97 for Tyler standard screen-scale sieves are given in Table 98.

The following is an example of the application of Stadler's method to a crushing problem.

Example. A 4.5-ft. × 16-in. conical ball mill fed with quartzite having the screen test shown in column 2, Table 99, breaks to the size shown in column 3 at the rate of 36 tons per 24 hours with a consumption of 18.5 hp. Total energy units of feed = 487.82 (column 5) and of product = 1376.66 (column 6). The relative work done per unit weight of feed equals 1376.66 − 487.82 = 888.84.

$$E = \frac{888.84 \times 36}{100 \times 18.5} = 17.30.$$

Rittinger's law states that the work required to produce material of a given size from a larger size is proportional to the new surface produced. Richards (*TB*) develops the application as follows: The number of planes of fracture necessary to break a cube whose edge is one unit in length into

Table 97. Formulas for crushed-rock constants

	P	S	V	F	N
P		$\frac{U^3}{S^3}$	$\frac{U^3}{V}$	$\frac{(F + 3U^2)^3}{27U^6}$	R^N
S	$\frac{U}{P^{1/3}}$		$V^{1/3}$	$\frac{3U^3}{F + 3U^2}$	$\frac{U}{R^{\frac{N}{3}}}$
V	$\frac{U^3}{P}$	S^3		$\frac{27U^9}{(F + 3U^2)^3}$	$\frac{U^3}{R^N}$
F	$3U^2(P^{1/3} - 1)$	$3U^2\left(\frac{U}{S} - 1\right)$	$3U^2\left(\frac{U}{V^{1/3}} - 1\right)$		$3U^2\left(R^{\frac{N}{3}} - 1\right)$
N	$\frac{\log P}{\log R}$	$\frac{3(\log U - \log S)}{\log R}$	$\frac{3\log U - \log V}{\log R}$	$\frac{3[\log(F + 3U^2) - \log 3 - 2\log U]}{\log R}$	

U = length of edge of assumed unit cube. S = length of edge of any given cube (= screen aperture). P = number of cubes of edge S in unit cube. V = volume of cube of edge S. F = area of fracture or new surface produced in breaking unit cube into P cubes of side S. R = ratio of increase in volume of particles from one screen size to the next in the sieve scale used. N = ordinal number of screen size.

a Column (5) = Column (2) times column (4). *b* Column (6) = column (3) times column (4).

n^3 smaller cubes with edges $1/n$ units in length is $3(n-1)$. See Fig. 44. The area of each such fracture plane is one. If the work done to produce fracture along one such plane is B, then the total work done in the subdivision indicated is $3B(n-1)$. Generalizing, if D is the edge of the original cube and d that of the resulting cubes, n becomes D/d; the area of each fracture plane is D^2, and the formula for work done becomes

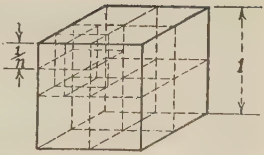

FIG. 44.—Theoretical breakage of a cube.

$$W = 3BD^2\left(\frac{D}{d} - 1\right).$$

The number of cubes D inches on an edge contained in a 1-inch cube is $1/D^3$ and the work per cubic inch for breaking cubes of any size D to cubes of any smaller size d is

$$W = \frac{1}{D^3}\cdot 3BD^2\left(\frac{D}{d} - 1\right) = 3B\left(\frac{1}{d} - \frac{1}{D}\right).$$

When, as is the case in rock crushing, the particles are irregular in shape, a multiplier K must be used, representing the ratio between the surface of a mass of ore consisting of particles that will pass a given rectangular opening and the same mass existing in such theoretical cubes as will just pass the same opening. The formula then becomes

$$W = 3KB\left(\frac{1}{d} - \frac{1}{D}\right).$$

Richards states that K varies from ½ to ¼. He also gives the following method for determining B in any particular case.

Example. Let S = sp. gr. of rock. Then $55320/S$ is the number of cubic inches of rock of sp. gr. S in a ton.

$$W = \frac{55320}{S}\cdot 3\,KB\left(\frac{1}{d} - \frac{1}{D}\right) \text{ ft.-lb. per ton}$$

$$= \frac{0.08382\ KB}{S}\left(\frac{1}{d} - \frac{1}{D}\right) \text{ hp.-hr. per ton.}$$

If now, by experiment, the number of hp.-hr. per ton expended in crushing the ore in question from an average diameter D to an average diameter d is determined and substituted for W in the last equation, and proper values for K and S are likewise introduced, the value of B for the given ore may be obtained.

It is to be noted that the figure substituted by Richards for W is not the useful work done, but includes also the work done in overcoming friction. B, therefore, as thus determined, applies only to the particular experiment.

Del Mar (*94 J 1129*) gives the following statement of Rittinger's law: "The work required to crush rock is very nearly proportional to the reciprocals of the diameters crushed to." He applies this law to a crushing problem as follows:

Example 1. Comparison of efficiency of two mills. Mill No. 1 crushes 2.5 tons per hp.-hr. and mill No. 2, 3.0 tons per hp.-hr. Sizing tests of feed and product and energy calculations are given in Table 100. The surface produced per unit weight of material by mill No. 1 is 21,111 minus 16,012 or 5099 units; similarly by mill No. 2, 3737 units. The units of reduction produced per hp.-hr. by mill No. 1 equals 5099 times 2.5 or 12,747.5; by mill No. 2, 11,211. Mill No. 1 is, therefore, more efficient by 13.7 per cent., based on the performance of mill No. 2.

Example 2. Comparison of efficiencies through various screens. If it is desired to know which of the mills compared in the preceding example is most efficient in crushing through a given screen, with no weight given to the character of material passing the screen in question, the method of calculation is shown in Table 101. Column (*l*) in the table is obtained by multiplying the differences between the corresponding numbers in columns (*e*) and (*g*) by 2.5, the tonnage crushed per hp.-hr. Similarly column (*m*) is obtained by multiplying the differences between columns (*i*) and (*k*) by 3.0. The table indicates that in crushing through 20-mesh, 40-mesh and 60-mesh, mill No. 2 is the more efficient; crushing through finer meshes, mill No. 1 is better.

Gates' crushing-surface diagram. In presenting a graphical method of comparing crushing efficiencies according to Rittinger's law, Gates (*95 J 1039*) says:

" . . . the energy absorbed by a lot of given sized particles is proportional to the product of their surface by their weight, which can be shown graphically by an area. And if we have a series of these areas, placed side by side, and representing the summation of the energies of the different sizes produced by a crushing operation, the total area is proportional to the energy expended on the rock. And when the cumulative weights of the different sizes are plotted consecutively, as in Fig. 45, the area between the sizing-analysis curve and the zero lines is proportional to the work expended on the rock in breaking it down from the infinite mass. And then as further crushing takes place on all or part of this rock and the new sizing-analysis is plotted, the area between the two curves is proportional to the further work done. This is the crushing-surface diagram."

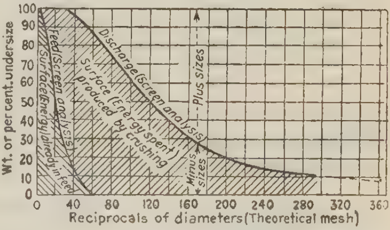

Fig. 45.—Crushing-surface diagram (*after Gates*).

In another article (*97 J 795*) Gates introduces a method for applying the crushing-surface diagram to a determination of crushing efficiencies. He defines a MESH-GRAM as a surface unit

" produced by a theoretical crushing operation in which one gram of particles of the same diameter is all reduced to a diameter whose reciprocal is one greater than before reduction."

Thus one gram of particles 0.1-in. diameter (reciprocal, 10), if crushed to particles 0.05-in diameter (reciprocal, 20), would result in the production of 10 mesh-grams of new surface. If the quantity so crushed were 1 ton, the new surface produced would be 10 mesh-tons. If, now, sizing analyses of the feed and product of a crushing operation are plotted with cumulative percentages as ordinates and reciprocals of diameters as abscissas (see Fig. 45) and the area between the feed and product curves is measured, this area, in terms of the scales used, will represent a certain number of MESH-PER CENT. of new surface produced, equal to 100 times the change in average size expressed in THEORETICAL MESH (= reciprocal of diameter). This figure multiplied by the tons crushed per horsepower-day gives MESH-TONS PER HORSEPOWER-DAY.

Example. Fig. 46 is plotted from data given in Table 102. The area between curves H_p and H_f and the ordinate 333 is 95.7 unit squares on the diagram and that between the same ordinate and curves C_p and C_f is 78.3 unit squares. Each unit square represents 200 mesh-per cent. Hence the new surface exposed by the Chilean-mill crushing is 15,660 mesh-per cent. and that by conical mill crushing, 19,140 mesh-per cent. The Chilean mill crushed 2.25 tons per hp.-day and the conical mill, 2.50. Multiplying 15,660 by 2.25 and 19,140 by 2.50, dividing in each case, also, by 100 to eliminate percentage, gives 392 mesh-tons per hp.-day as the performance of the Chilean mill, compared with 478 mesh-tons per hp.-day for the conical mill.

Table 102. Comparative screen analyses of conical pebble mills and Chilean mills at Miami Copper Co. *(47 A 50)*

Kick *vs.* **Rittinger.** Controversy has raged for several years as to the correctness of the volume or surface method in estimating the useful work done in crushing. Details of the arguments may be had by reading the papers previously cited in this article and the citations in this paragraph. Convincing experimental data are lacking. The advocates of Rittinger's law in no place show that they consider the factor of distance in the equation "*work = the force applied multiplied by the distance through which it acts*," and the printed argument apparently neglects this essential element. Advocates of Kick's law must admit that the relation "*work done is proportional to the volume ratio of the particles in the feed and product*" can only be true if the rock breaks at or near the elastic limit, and that the further from the elastic limit fracture occurs, the weaker becomes the theoretical foundation for the methods based on Kick's law. But in any case, up to the elastic limit, Kick's law is in accord with accepted physical conceptions, and its weakness beyond the elastic limit in no way strengthens the position of the Rittinger advocates. The methods based on Rittinger's law credit the crusher with a much greater amount of useful work in producing very fine material than do those based on Kick, and, therefore, show higher efficiencies for fine crushing. Bell *(57 A 133)* presents the experimental data and calculations summarized in Table 103 to show that a gyratory crusher breaking from 3.5-in. to 1.0-in. and rolls breaking from 0.07-in. to 0.04-in. are working with substantially equal efficiency, according to the Rittinger method of calculation, while according to the Kick method the efficiencies are 710 and 52 respectively. He argues from this that because the Rittinger method indi-

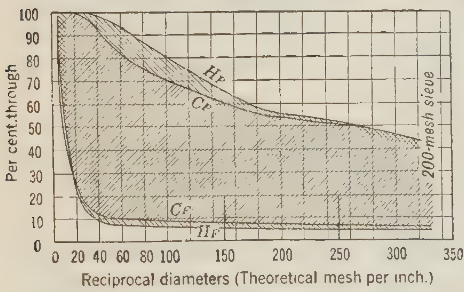

FIG. 46.—Application of Gates method to the data in Table 102.

cates that the amount of crushing done by a measured horsepower is the same whether the material being crushed is fine or coarse while the Kick method indicates more crushing per measured horsepower in breaking coarse material, the Rittinger method is correct and the Kick wrong. But the inefficiency of rolls crushing from 0.07-in. to 0.04-in. is notorious and the comparative efficiencies indicated by the Kick figures are much the more reasonable. Haultain, who has probably done more experimental work on the subject than anyone else, summarizes his conclusions (*69 A 183*) as follows: The energy usefully employed, neglecting friction and inertia losses in the machinery, is absorbed principally as (1) energy of new surface produced, (2) heat attendant upon deformation without breaking, (3) heat resulting from friction between particles and between particles and crushing surfaces. Neither method measures this absorbed energy accurately; the mean of the two is probably more nearly correct than either for roll crushing; no simple formula is applicable to all rocks and all methods of crushing. See also A. O.

Table 103. Comparison of work of crushing calculated according to Stadler, Kick and Rittinger methods by Bell

Crusher	Diameter of feed, inches	Crusher opening, inches	Work done per A.E.H.P.(*a*) per 24 hr.

Rolls	0.11	0.04	89	1187
Rolls	0.07	0.04	52	823

a Apparent effective horsepower.

Gates (*52 A 875*). A. M. Gaudin (*73 A 253*) recommends using the ratio of the energy of the new surface produced to the energy input as a measure of efficiency, thus charging the machine with items (2) and (3) above. The difficulty with this method lies in evaluating the surface energy of the broken rock. Based on figures for surface energy of solid quartz (*Fourth rep. on colloid chemistry, Brit. Assoc. Adv. Sci., p. 281*), Gaudin's figure for the efficiency of dry ball-milling from −0.5 +0.065-in. to 98 per cent. −200-mesh is 0.6 per cent. Bureau of Mines investigators, using a falling ball as the crushing force and rate of solubility as a measure of new surface produced have found that the relation between the force applied and the new surface produced is linear.

Choice of methods of comparison. When the operations to be compared are closely similar, both as to size of feed and size of product, it does not make any difference in the conclusion reached whether the Kick or Rittinger method is used. When, however, there is considerable difference in the character of the material entering and leaving the competing machines, the comparative efficiency of the finer crusher will be relatively higher by the Rittinger method. This will lead to the conclusion that economy will be gained in a crushing installation by putting more and more of the burden of crushing on the fine-crushing machines, a conclusion that is open to most serious question.

SECTION 5

SIZING

1. Introduction

Definitions. SIZING is the process of division of a mixture of grains of different sizes into groups or GRADES whose characteristic is that the particles therein are more or less nearly of the same size, that all have passed an aperture of certain dimensions and failed to pass through some smaller aperture. The screen through which the particles have passed is called the LIMITING SCREEN; that which has retained them is sometimes called the RETAINING SCREEN. CLOSE SIZING is practiced when the limiting and retaining screens are of nearly the same aperture. A mass of particles is said to be a NATURAL PRODUCT when it has all passed a given limiting screen but has been subjected to no further treatment. Material that stays on a given screen is the OVERSIZE or PLUS (+) of that screen; that passing is the UNDERSIZE or MINUS (−). A SIEVE SCALE is the list of apertures of successively smaller screens in a step-sizing operation. The SIEVE RATIO is the ratio of the aperture of a given screen in a given sieve scale to the aperture of the next finer screen. PERCENTAGE OF OPENING is the ratio of the combined area of the openings in a given area of screening surface to the total area of the surface. CLASSIFICATION is a process of approximate sizing in which a natural product is caused to settle through a fluid, usually water, but sometimes air, at rest or in motion. The settled products of a classifier are called SANDS or SPIGOT PRODUCTS according to whether the classifier is of the mechanical or hydraulic type, the fine overflowing material is called OVERFLOW or SLIME. Sizing with classifiers is discussed in Section 6.

Purposes of sizing: (*a*) to grade broken stone such as road metal, concrete aggregate, rock powders, etc.; (*b*) to remove fine material from crusher feeds and thus save power and prevent over-grinding; (*c*) to perform a step in a concentration process, *e.g.*, to size before jigging (see Sec. 9, Art. 1).

Principles. The fundamental elements in screening are the passage of undersize particles through the screen apertures and the rejection of oversize particles. In order to effect this choice, the particles must be brought to the openings and must be presented thereto at such a velocity and in such direction that passage of the undersize will not be hindered or prevented by rebound from the edges or walls of the opening. If every particle of undersize could be brought to an opening individually, at substantially zero velocity, in a direction perpendicular to the plane of the opening and with the center of its least projected cross-section in the line of the center of the aperture, and if

the screening surface had zero thickness, there would be immediate passage of every such particle. But tonnage demands forbid individual and low-velocity presentation, while mechanical considerations prevent perpendicular presentation and the use of screening surfaces of gossamer thickness. Practically, particles are crowded and continually interfering at the apertures, they are presented at considerably in excess of zero velocity, in a direction nearly parallel to the plane of the screen surface, with their maximum rather than their minimum projected surfaces parallel to the plane of the screen, and the screen opening has a depth frequently greater than the greatest dimension of the particle of undersize. As a result many undersize particles are prevented for a considerable time from access to an opening, others come to the opening from such a direction or with such orientation or at such velocity that they fail to enter, others entering are delayed in passage or stopped by friction against the walls of the opening.

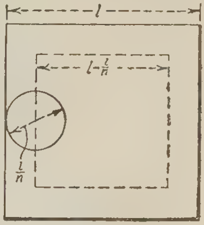

Fig. 1.

Chance rules the approach of a particle to hole or imperforate surface and the probability that the lowermost point of the approaching particle will strike hole rather than screen fabric is proportional to the percentage of opening in the fabric. Chance coupled with the relative dimensions of particle and opening rules in determining the passage of a particle presented to an opening. The problem may be stated in mathematical form as follows: If, in Fig. 1, the full-line square whose side is l represents a square screen aperture and the circle a spherical particle whose diameter is l/n (n being any number greater than l), then the probability of passage without touching the side of the aperture is proportional to the ratio of the area of the smaller square to the area of the larger, $= P = \left(\frac{n-1}{n}\right)^2$ and the probability that a grain will touch the side on presentation is $(1 - P)$. On the assumption that if the center of the particle falls within the inner square in Fig. 1, the particle will surely pass, while if it falls without this square, it will fail to pass, the values of P for different values of l/n are measures of the ease of screening particles of l/n diameter through l-sized square apertures and $1/P$ gives the number of such apertures side-by-side that should be provided. The first part of the assumption is true if l^2 is the area of the opening projected on a plane at right angles to the path of the particle; the second part must be modified in favor of passage, because although a particle presented with its center in the space between the squares will rebound in a direction and through a horizontal distance dependent upon the

shape of the edge of the aperture, the angle of approach, the velocity of approach and the shape of the particle, nevertheless some of the rebounding particles will fall with their centers within the inner square and pass. On the other hand, reduction in size of effective aperture by reason of screen inclination, acuteness of angle of approach of particle, interference by another particle of undersize simultaneously presented, and covering of part of the opening by oversize particles, all decrease the opportunities for passage. None of these modifying factors is capable of mathematical statement, hence the equation serves merely as a means of indicating the probable effect on rate of screening of the ratio of particle size to aperture. To this extent Table 1, derived from the formula, is illuminating. It indicates that as the particle size approaches that of the aperture the difficulty of passage becomes extremely great, even excluding all factors other than pure chance that militate against passage. Warner (*70 A 631*) gives the data summarized in Table 2 as the results of a test in which a sample of broken rock was screened on a standard 4.699-mm. testing sieve in a Ro-Tap shaker (Sec. 22, Art. 2) and the undersize products passed during the successive screening intervals were separately

collected, weighed and subjected to analysis on a 3.327-mm. screen. This work is qualitative confirmation of the theory, modified, however, by the practical elements of crowding, particle velocity, etc., as previously enumerated. The column headed "Increment per sec., grams +3.327-mm." holds the key to the operation from the point of view of screening rate. In the first three intervals the passage of even the smallest particles was interfered with by the mass of smaller material going through. By the time the fifth interval was reached most of the −3.327-mm. material had passed and by the end of this interval the bulk of the finer part of the +3.327-mm. material had also gone through. From that time there was a marked decrease in the rate of screening corresponding remarkably in order to the last four items in Table 1 and indicating that the material passing the screen in this part of the operation was of a size about 0.9-times the diameter of the screen opening and upwards.

The important fact as regards capacity in close sizing is the proportion of undersize or oversize that is of nearly the same size as the aperture. Undersize much smaller than the screen openings passes through very rapidly, so rapidly in fact that, if it is given free access to the holes, it goes through almost like water, and no normal variation in the amount of such material has any effect on screen capacity. Likewise particles much coarser than the openings, when sliding over a screening surface, have such large interstitial spaces with comparison to undersize particles that the latter pass down freely to the screen surface. But when the proportion of particles of a size near that of the screen aperture is large, these particles, which have interstitial spaces that are relatively small, hold back the fine material from the screen; the particles only slightly larger than the screen apertures wedge in and cause blinding, and those only slightly smaller than the aperture pass through with difficulty, therefore slowly. The result, as shown by Warner's work and the above theoretical analysis is marked reduction in screen capacity.

The velocity of approach of particles to the screen together with the direction of approach have a marked effect on screening rate. If a spherical particle is traveling at a given rate along a screening surface whose apertures are several times the diameter of the particle, as in Fig. 2(*a*), its path upon leaving the support of the screen fabric will be somewhat as illustrated and the particle will pass through. With a smaller aperture the same particle will strike the far edge of the opening. If the particle is perfectly spherical and elastic and the aperture has square edges and vertical sides, such particle, as pictured in Fig. 2(*b*), will also pass; but with irregular particles and with apertures having rounded edges and converging sides there is every reason to expect that a particle following the path illustrated would fail to pass through. If the initial approach of the particle is from above and at an angle to the screen surface as illustrated at (*1*) in Fig. 2(*c*), the direction of approach and high velocity both aid in passing the particle, if it strikes an opening, but if it fails to do so, as at (*2*), then high velocity, by causing the particle to bound, will tend to defer its opportunity to pass and thus decrease screening rate. Since the percentage of opening in screens is usually less than 50, the evil effect of bounding may be expected to overbalance the good.

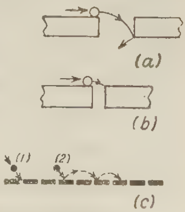

Fig. 2.

When, as in all practical screening operations, a mass of particles many grains deep is presented to a screen surface, coarse and fine grains are likely to be mixed indiscriminately, with the result that many oversize particles are

in contact with the screen and many undersize particles are supported in the mass above and away from the screen surface. If the particles are free to move among themselves, *i.e.*, if the material is not sticky, any subsequent movement of the mass will cause rearrangement of the particles. If the movement is sufficient to enliven the mass thoroughly without lifting it bodily from the screen, stratification occurs, with the finer particles at the bottom and the coarsest on top. Such stratification is essential to screening and is as much the purpose of the motion imparted to screening surfaces as are transport of oversize and prevention of blinding. Excessive movement, while it increases the ability of the screen to move material across its surface, defeats stratification and thereby decreases screen efficiency.

2. Screening efficiency.

Methods of reckoning screen efficiency are not uniformly established. The usual method is to express efficiency as the ratio of the weight of undersize obtained to the weight of undersize in the feed. This latter figure is determined by screening a feed sample on a hand screen of the same aperture as that of the screen under investigation, or by making a sizing test of the feed on the usual testing sieves, interpolating for the aperture of the operating screen and multiplying the percentage of undersize thus obtained by the tonnage treated. Weighing feed and undersize can be obviated by making screen analyses of representative samples of feed and oversize. The recovery formula (Sec. 22, Art. 15) then applies and efficiency $= E = 100\left(\frac{100(e - v)}{e(100 - v)}\right)$ where e and v are percentages of undersize in feed and oversize respectively. On this basis of calculation, Wiard (*14 CME 191*) states that the average efficiency in commercial practice is about 60 per cent., that 75 per cent. is extremely good work and 90 per cent. about as high as can be reached by hand screening. Warner criticizes the use of this formula on the basis of the experimental work shown in Table 2. He argues, correctly, that it does not take into consideration sufficiently the fact that 1-mm. material is readily passed through a 10-mm. screen while 9-mm. material passes the same screen with great difficulty, and suggests that the screen analysis of feed and of oversize concern itself only with the DIFFICULT GRAINS, which he defines for this purpose as those held on the next finer Tyler standard sieve-scale testing sieve whose aperture is less than 83 per cent. of the aperture of the sieve under investigation. He then applies the recovery formula in the form $E = \frac{U(F - O)}{F(U - O)}$, where F, U, and O are percentages of difficult grains in feed, undersize and oversize respectively.

In many places the practical efficiency of a screen is sufficiently measured by the percentage of undersize in the oversize. This is particularly the case when the screen is preparing feed for jigs, or returning oversize for re-grinding, or preparing for sale a product against which there are rigid specifications as to percentage of undersize.

Efficiency is markedly decreased by high feed rate, especially if accompanied by high percentages of oversize and difficult grains, because on a heavily loaded screen, fine material has difficulty in getting down to the screen surface and blinding is caused by wedging of particles into the screen openings on account of the weight of the bed.

Screen cloth should be tightly stretched, because material piles up and forms thick layers in depressions. Dry ore screens better if warm (100–150° F.).

3. Screening surfaces

There are three varieties of screening surfaces: parallel rods, punched plates, and woven-wire or silk cloth. The minimum clear space between the

a Washburn and Moen gage, see Table 3. *H* Heavy.

edges of the opening in a screening surface is called the APERTURE or SCREEN SIZE. Aperture is expressed in several ways. The best way, undoubtedly, is to give the dimension in inches or millimeters; the commonest, particularly with woven screens, is to express it as so many MESH, meaning the number of openings in the screen per linear inch. This latter method is definite only when coupled with a statement of the size of wire, or when referred to one of the testing-sieve scales (Sec. 22, Art. 2). When size of wire is given it should be expressed in ordinary units of measure, *i.e.*, inches or millimeters; if gage numbers are used the gage must be named, on account of the differences in dimensions corresponding to the same gage number in different gage scales. See Table 3. Given two of the quantities a = aperture, d = diameter of wire, and m = mesh, the percentage of opening, P, and the other quantity can be determined from the following relations:

$$P = a^2m^2 = \frac{a^2}{(a + d)^2} = (1 - md)^2;\ m = \frac{1}{a + d};\ a = \frac{1}{m} - d;\ d = \frac{1}{m} - a.$$

The mesh of punched-plate screens does not mean the number of openings per linear inch of punched plate but rather that the aperture has a dimension near that of some woven-wire screen of the given mesh. The equivalent woven-wire screen is usually a medium-weight screen. If the largest and smallest apertures corresponding to a given mesh in Table 4 are averaged, the result will be close to the punched-plate aperture called by that mesh. Certain districts, notably South Africa, express aperture as SQUARE MESH, *i.e.*, the number of apertures per square inch, which is even less informing than the usual American terminology. NEEDLE MESH is a number used to designate an aperture and corresponds to that of a needle of the same or nearly the same diameter as the dimension of the opening. See Table 5. This is

Table 5. Needle mesh

Needle number	Largest diameter of head, inch	Equivalent screen
1	0.0735	10-mesh.
2	0.0428	16-mesh; No. 3 slot.
3	0.0395	16- to 18-mesh; No. 3 to No. 4 slot.
4	0.0355	20- to 24-mesh; No. 4 to No. 5 slot (nearer the last).
5	0.0335	20- to 24-mesh; No. 4 to No. 5 slot (nearer the last).
6	0.0300	24-mesh; No. 5 to No. 6 slot.
7	0.0265	24- to 26-mesh; No. 6 to No. 7 slot.
8	0.0230	26-mesh; No. 8 slot.
9	0.0203	29-mesh; No. 9 slot.

the acme of inconvenience, although actually more precise than mesh designation. Table 4 gives dimensions of square-mesh steel-wire cloth corresponding to mesh designations and showing the possible range in aperture for a given mesh cloth of standard manufacture. Table 6 gives dimensions corresponding to wire-gauge numbers in column 7 of Table 4. To determine the aperture of intermediate screens within the ranges given in Table 4 proceed as follows: From Table 6 pick wire of a number included within the range of column 7 of Table 4. Substitute the corresponding diameter in the equation $a = 1/m - d$ (see above).

Materials. Square-mesh wire screens of substantially the same meshes and apertures as listed in Table 4 are obtainable in brass, copper, bronze, nickel and Monel metal, although all of the heavier screens are special and very rarely made. The screening surface must be strong enough to carry

the load and it should resist, so far as possible, abrasion and corrosion. At the same time it should be cheap. When corrosion is not a factor screens are normally made of high-carbon steel and in certain cases of special alloy steels. Steel is stronger and resists abrasion better than any other material available. When corrosion must be resisted, iron, copper, bronze, Monel metal and other alloys are used. Such materials cost much more than steel initially, and are not so highly resistant to abrasion. Their use is justified only when the final cost, by reason of their greater resistance to corrosion, is less than that of steel screens.

Punched plate was formerly used more widely than at present. It consists of metal plate symmetrically punched with apertures that will pass particles of the desired size and hold back all larger. Methods of arranging holes and various shapes of holes are shown in Fig. 3. Substantially any

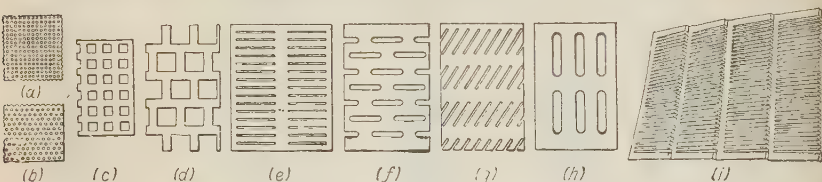

FIG. 3.—Types of punched-plate screen.

desired length is obtainable (limited only by the maximum lengths of rolled plate). The usual widths are 3 to 4 ft. but 6-ft. widths can be had. Maximum thickness is limited to about ½ in. by difficulty in punching. Apertures in punched plate are circular in most coarse screens, the circular form being used because it is cheaper to punch than the square and yet has 90 per cent. as much clear opening for a given strength of screen. Due, however, to the fact that the effective area of circular openings is so small in fine screens (see Table 7), slotted openings are most commonly used in these screens. The product of a slotted screen is not so irregular as the shape of the slot would indicate for the reason that most ores break in more or less granular fashion and there are relatively few needle-like or platy particles to take advantage of the slotted hole.

Very fine screens are so punched that the punch does not go completely through and remove a definite particle of metal but merely breaks or tears apart the plate, leaving a decided burr on the lower side. Holes in clear-punched plates diverge toward the die side. All punched-plate screens should be fed onto the side having the smaller opening in order to give a flaring passage that will tend to discharge freely all material that enters. Slotted screens are less easily clogged than square- or round-punched. Round holes retain smaller particles than square or slotted holes of the same clear aperture.

Roesler (*99 J 493*) showed that a square aperture in wire cloth would pass particles of the same size as a circular aperture whose diameter was 1.23 times the edge of the square opening.

The arrangement of round holes at the corners of equilateral triangles gives a greater percentage of opening than the arrangement with holes at the corners of squares. For diagonal spacing $P = 0.905d^2/(s + d)^2$; for square spacing $P = 0.785d^2/(s + d)^2$, where d = diameter of hole and s = least

Table 7. Typical punching for round-hole plate screens

width of clear metal between holes. With holes ½-diameter apart, diagonal spacing gives 40 per cent. discharge area against 35 per cent. for square spacing; with holes one diameter apart the corresponding percentages are 22.5 and 20.

Table 7 gives the essential data concerning the usual sizes of round-hole punched-plate screen. It is usually more economical to use thinner plate than that given in the table except on coarse sizes, since such plate offers less resistance to the passage of undersize grains. Table 8 gives sizes and weights of needle-slot screens. Table 9 gives the usual sizes of holes and spacing in oblong-hole punched plate.

Table 8. Needle-slot screens (*Harrington and King Perforating Co.*)

a This is for usual punching. Other punching may be had on order. *b* Slots 1$\frac{1}{32}$ in. long.

Percentage of opening for hit-and-miss endways punching is

$$P = \frac{1}{4}\left[\frac{\pi d^2 + 4d(l - d)}{(s + d)(l + 0.866s - 0.134d)}\right],$$

where d = width of opening, s = spacing at sides and ends of slots and l = length of slots. For straight punching and hit-and-miss sideways (Fig. 3(*e*) and 3(*f*) respectively) the formula is

$$P = \frac{1}{4}\left[\frac{\pi d^2 + 4d(l - d)}{(s + d)(s + l)}\right].$$

Advantages of punched-plate screens are stiffness, strength, freedom from blinding, and long life. Long life is gained, however, by making the plates thick and allowing the screens to wear until the metal between holes breaks. There is thus a large variation in size of opening between new and old screens and close sizing is sacrificed. Blinding increases as the holes become hopper-shaped through wear. Punched plate is heavy, hard to handle,

and if it is to be used on trommels (Art. 5) or other curved screening surfaces, must usually be rolled to the proper curve at the factory, making a bulky shipment.

Punched plate is widely used for coarse screening, down to, say 0.5-in. aperture, and on certain machines such as coal shakers, the stamp battery, Chilean and Huntington mills, it is used for fine screening. The usual sizes and weights for coal-dressing are given in Table 10; plate for ore and rock screening is usually heavier on account of greater wear. Coarse screens for trommels are frequently made of cast manganese steel, usually with round holes.

Such covering for a 48-in. × 14-ft. trommel at TONOPAH BELMONT (*52 A 110*) weighed 3776 lb., cost $572.30 (1915), lasted two years, and screened 300,000 tons.

Comparison of slotted and round-hole punched plate. Handy (*94 J 1123*) reports comparative performances on trommels at the BUNKER HILL AND SULLIVAN mill. Table 11

Table 11. Comparative sizing tests of oversize on slotted and round-hole punched plate. (*After Handy*)

Sizing screen, mm.	Oversize from 10-mm. round-hole screen, weight, per cent.	Oversize from 7-mm. slotted hole, weight, per cent.

−5	0.5	....

shows screen tests of oversize from the two types of covering on trommels taking the same feed. This shows that the 7-mm. slot lets through more undersize than a 10-mm. round hole, thereby working at higher efficiency both in production of −7-mm. material and in producing clean oversize. Table 12 shows that a round-hole plate of a given opening retains

3 to 4 times as much undersize as a slot-punched plate of the same opening. In all of these tests the slots were punched at right angles to the direction of the trommel axis and were of such length that the clear horizontal projection with the plate on a 20° slope was a circle. The slotted screens blinded much less than the round-hole.

Lip screen is shown in Fig. 3(*e*). It is a recently devised form of punched plate with slotted openings diverging in the direction of flow, the plate being bent downward near the lower end of each row of slots to form a drop in the general screen surface. The result is that particles that tend to wedge in the slots are pushed down to the bend and there readily freed. This type of screen surface is increasing in popularity for coal screening. It is thought to cause less breakage and abrasion than any other type.

Woven-wire screen is made with square and rectangular meshes. (See Fig. 4.) It is obtainable in any length and in widths up to 4 ft. Both warp

and filler wires are crimped to prevent distortion of the openings in service. Woven-wire cloth with slot-shaped apertures is manufactured and widely used at the present time under such names as TON-CAP and REKTANG. Fine screening on trommels, shaking and vibrating screens, etc., is nearly all done through woven-wire screening surfaces and woven wire is also used in place of punched plate

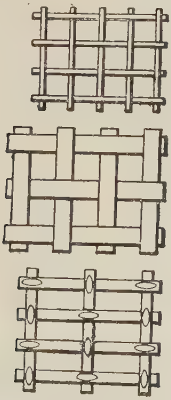

FIG. 4.—Double-crimped woven-wire screen cloth.

for much coarse screening. Table 4 gives the usual sizes and weights of square-mesh woven-wire screen and Table 13 gives sizes of one make of slotted mesh. There is very little slot-mesh woven-wire screen used coarser than 0.75-in. and very little finer than 48-mesh. The heavier screens in each size are used for rock and ore screening, the intermediate and lighter weights for coal screening, and the lightest for organic or very light mineral products. A covering of soft rubber tubing for the wires of coarse screens has been found at one or two plants to increase the life materially.

ranges. In the 3-in. size there is little to choose between the several types of equal weight. From 2-in. to 0.5-in. inclusive there is considerable difference in favor of plate, as compared to square-mesh wire, the slot-punching giving the greatest opening, but in the 0.75-in. and 0.5-in. sizes the heavy slot-mesh has as much open space as the slot-punched plate. From 0.25-in. to 0.10-in. inclusive, slot-punched plate and heavy slot-mesh wire screen have substantially equal and the greatest amount of opening, with round-punched plate intermediate and heavy square-mesh wire the least. In the finer sizes, for screens of equal weight, slot-mesh woven wire has the greatest opening, needle-slot plate is intermediate, and square-mesh wire screen has the least, except in the two finest sizes. Throughout the range of sizes slotted screens have a greater percentage of opening than square- or round-hole.

Table 15 (*40 MEW 595*) shows the effect on screening capacity of difference in percentage of opening in screens of the same aperture. This test was made with different screens on a 5-stamp battery, the drop of stamps and water flow being maintained constant in the three cases.

Table 15. Effect of percentage of opening on screen capacity and product

Mesh	24	30	40
Aperture	0.0176	0.0173	0.0178

Tons crushed per 24 hr., by 5 stamps	10.8	14.6	16.4

Cloth screens of silk are light, elastic, flat and have a relatively large percentage of opening but are expensive and fragile. They are used for very fine dry screening. Table 16 gives the usual sizes and numbers.

At AMERICAN GRAPHITE CO. (*120 P 569*) it was found that for cleaning graphite-flotation concentrate on 100-mesh silk lasted much longer than wire.

Size of the product of a screen is by no means equal to the nominal dimension of the opening through which the product has passed. The maximum possible cubical particle that can be passed through a circular opening of diameter d has an edge $0.71d$. Larger platy or rounded particles can pass. Roessler has shown that on several different kinds of materials the average maximum size of the particles passing a round hole is only 81 per cent. of those passing the same size of square hole. When a screen is tilted the effective aperture is reduced substantially to that of the horizontal projection of the inner edges of the actual aperture. The amount of reduction in effective aperture depends upon the amount of tilt and the thickness of the screen plate or cloth.

Arthur Crowfoot (*PC*) states that at No. 6 Concentrator, MORENCI BRANCH, PHELPS-DODGE CORPORATION, a 0.280-in. aperture is used to produce a 0.185-in. product on Hummer screens set at 38° from the horizontal. Holbrook and Fraser (*Bul. 234 USBM*) state that ¼-in. screen at 45° made a ⅛-in. product. and that at 35° slope round-hole screens pass a product whose maximum-sized particles are about two-thirds the diameter of the hole. Referring to concentrating practice, they say that in one mill a 30-mesh wire cloth at 45° gave 50-mesh maximum undersize and that a 1-in. round-hole plate at 45° produced – ½-in. undersize. Under such circumstances, however, the undersize will contain TRAMP OVERSIZE, *i.e.*, occasional particles considerably larger than the average maximum, that work through because of some irregularity in the direction or velocity of presentation.

An apparent exception to the rule is presented by rectangular-mesh woven-wire screen which, if set with the long dimension of the aperture at right angles to the direction of slope, presents substantially the full aperture to material flowing down slope. This is shown in Fig. 5. Bland (*107 J 1114*) states that while 20-mesh cloth on some vibrating screens delivers −40-mesh product, the screening is incomplete, difficult grains are not passed, and while the oversize from hand screening will be shown to contain 40-mesh grains the undersize will contain 20-mesh grains. He states further that an inclination of 35° will decrease the effective dimension of the opening less than 10 per cent. rather than upwards of 18 per cent. as would be indicated by the geometrical solution. Table 17 is an empirical table, showing the sizes of maximum particles that are to be expected in a product screened through apertures of various diameters. In the smaller sizes particularly it is necessary to increase the screen apertures as much as 100 per cent., if the ore is damp and sticky, in order to pass the same maximum-size particles.

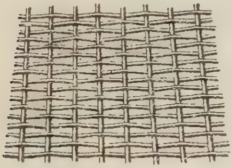

FIG. 5.—Rectangular-mesh wire cloth viewed from an acute angle.

a Intermediate dimension of roughly three-dimensional particles. *b* 40° to 45°.

TYPES OF SCREENS

Screens are classified on the basis of their method of support as FIXED and MOVING. Fixed screens are placed at any angle from 0° to 45° from the horizontal. When set at the smaller angles they are meant to retain the oversize for treatment such as sledging or hand-picking, and material must be worked over and through them manually. Fixed screens are used for both coarse and fine screening, although usually in the former service. Moving screens are of many forms, but most of them may be placed in one of the four classes: shaking, vibrating, revolving, traveling-belt. Fixed screens are almost invariably run dry; moving screens are run either wet or dry. Neither type will operate satisfactorily on damp material.

4. Grizzlies and fixed screens

Fixed screens with the screening surface made of parallel rods are known as grizzlies. Their economical use is limited to coarse screening (aperture 2-in. and upwards). A typical grizzly as sold by the supply houses is shown in Fig. 6. The bars are usually held together by bolts at right angles to their length and are spaced the desired distance apart by means of thimbles or sleeves on the bolts. The bolts should be spaced about 2 ft. with heavy, coarse ore, otherwise the bars will spread unless they are very stiff. The disadvantage of this type of screen is clogging due to the retarding effect of the cross pieces. This disadvantage may be overcome by making the bars of greater depth and holding them in comb-like cross plates with one through-bolt near the head end to keep them in place.

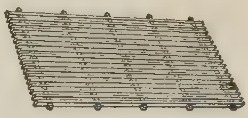

Fig. 6.—Fixed grizzly.

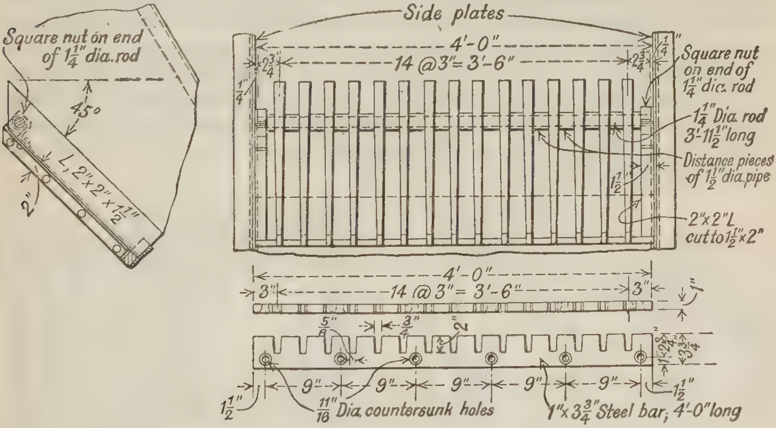

Fig. 7.—Tapered grizzly bars with depressed supports. (Miami Copper Co.)

Fig. 7 shows such an arrangement adopted by the Miami Copper Co. Another form is shown in Fig. 8. Soft steel bars 1 × 5-in. are clipped to heavy 4 × 4-in. cross supporting angles with heavy angle clips. This method of construction brings the cross bars well below the path of most particles and eliminates interference with the flow of particles. The particular grizzly shown was fed with maximum-size lumps weighing from 100 to 150 lb. and falling approximately 2 ft., yet the bars are said to have been capable of wearing to 2 in. in height before it was necessary to replace them. (*98 J 1045.*) Bars that taper along the run as shown in Fig. 7 tend to prevent clogging. Fig. 9 shows such a bar used by Ohio Copper Co. (*99 J 749.*) At Hol-

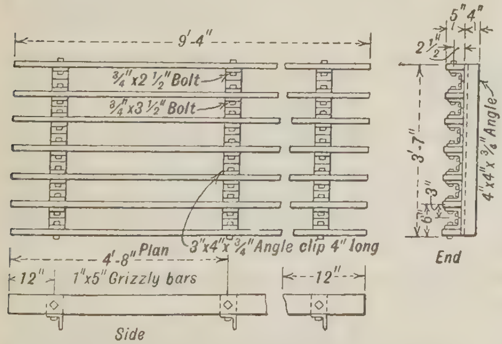

Fig. 8.—Grizzly with depressed cross bars.

LINGER MINES (*Bul. 119 CMI 341*) the bars are flared from 3.5-in. to 7.5-in. opening in a length of 8.5 ft.

Grizzly bars are made of wood, with or without metal protection, and of cast iron and steel. Various shapes are shown in Fig. 10. Other things being equal, the form of bar that gives minimum contact with the sliding material is best. The aperture of the standard taper-bar grizzly (Fig. 6) is favorable to screening, because the flare tends to pass everything that gets through the upper surface. The aperture changes as the bars wear, but as close sizing is not the aim in grizzly screening this fact is not so important as that when worn bars fail a considerable percentage of the weight of the new bar must be discarded. The diamond-headed form (Fig. 10, *f*) has the advantage of long wear with but little change in aperture or strength. A bar of this type with replaceable angle-shaped liners is probably the most economical form. At stamp mills, discarded stamp stems are commonly used. Around many mines old rails are made to serve. Normally these rails are merely sawed to length and set into the grizzly frames.

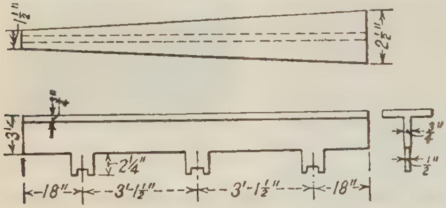

FIG. 9.—Tapered grizzly bar, OHIO COPPER CO.

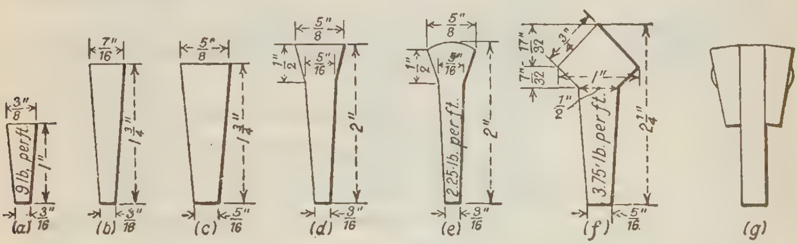

FIG. 10.—Grizzly bars.

At the HECLA MINE, Burke, Idaho (*106 J 24*), the flanges were cut from 85-lb. rails by means of an oxy-acetylene flame, leaving three wings 6 in. long and the full width of the rail flange, one at each end and one at the middle. These were bored and used for bolting the bars in place.

The use of such substitutes is, at best, a makeshift. They need more frequent renewal than the regular bars because they are made of milder steel, and the shape of the aperture is not ordinarily so favorable for screening.

Where the largest lumps in the feed are very much larger than the final size it is desired to pass through the grizzly, the arrangement employed in the QUINCY rock house (*100 J 103*) is useful. Skips dumped onto plates and the rock passed thence first over a short grizzly with 3-in. openings, then over a grizzly (in the same plane) with 6-in. round bars spaced 20-in. centers for taking out the largest lumps of feed. These passed to a drop hammer. The oversize of the 3-in. grizzly passed to the crushers and undersize to the stamp-rock bins. It was probably necessary to help some large lumps across the coarse grizzly, which was long (12 ft.) and set at 16° slope.

When heavy loads are to be dumped directly onto a grizzly, strength is an important factor in design.

At the Arthur mill of UTAH COPPER CO. (*118 P 469*) 50 to 80-ton cars are dumped by a revolving car-dumper directly onto a grizzly set at 35°. The bars are made of 12-in. @ 28.5-lb. I-beams, 32 ft. long, capped with special manganese-steel castings, set with 5-in. clear opening at the upper end and 6-in. at the lower. At ALASKA GASTINEAU (*63 A 493*)

10-ton cars were dumped four-at-a-time onto plates and thence passed over a 10-in. grizzly made of 8-in. I-beams with manganese-steel shoes. After 6,000,000 tons had passed over this grizzly some of the bars had to be replaced on account of bending but the shoes were still serviceable.

Slope of grizzly depends upon its purpose. A flat grizzly is used on top of ore bins fed by skips or cars in order to catch and hold lumps that are too large to pass the bin gates or enter the crusher until they can be sledged to proper size, as determined by the spacing of the grizzly bars. Grizzlies in the feed chute to primary crushers are set at such a slope that material will just slide over them (±30°) or will just not slide (±25°) so that the movement over them is readily controlled by the crusher tender, allowing him to remove waste of all kinds from the mill feed. To insure free movement of material, the slope should be from 35° to 45° or as high as 50° for sticky ores. A lower slope is used when material is delivered with an initial velocity in the direction of the slope.

Holbrook and Fraser (*Bul. 234 USBM*) have collected the following data on sliding angles that bears on the question of slope. Egg-size anthracite ($2\frac{5}{16}$ to $3\frac{1}{4}$-in.) will just slide uniformly on glass at $2\frac{1}{4}$ in. per ft., manganese bronze at $2\frac{5}{8}$ in., mild steel at 3 in. and cast iron at $3\frac{1}{2}$ in. per ft. (16° 15′). Slopes for anthracite are less than for bituminous coal and ores require more slope than either. Dry quartzite ran well on steel plate at 35°. Steel-lined chutes for Lake Superior copper ores are commonly 26° to 30°. Experimental results are given in Table 18. It must be remembered that blinding causes the screen surface to become rough and that steeper slopes than those given in the table mu t be used to overcome this difficulty. Table 19 shows common practice in coal dressing. Moist ores require 10 or 15° greater slope than dry. Concavely-curved bars have been used in coal-screening grizzlies, where it is desirable to discharge oversize with as low velocity as possible to prevent breakage.

Table 18. Sliding angles of various substances on bright steel. (*After Holbrook and Fraser*)

Material	Starting angle (static friction)	Angle on which material continued to run (kinetic friction)	Slopes used in practice
Pennsylvania anthracite:			
Egg size	15° 40′	14° 00′	14° to 16° chutes.
Chestnut size	16° 40′	15° 10′	18° to 20° chutes.
Southern Illinois coal:			
6-inch lump	21° 50′	20° 40′	22° 30′ chutes.
Run-of-mine	....	....	30° to 35° chutes.
Slack	25° 40′	22° 30′	30° to 45° chutes.
Oklahoma screenings	24° 00′	22° 30′	30° to 45° chutes.
Chestnut size (McAlester seam)	21° 00′	19° 00′	....
East Kentucky egg, 4×6 inches	21° 50′	20° 20′	26° 28′ bars.
Bituminous shale	21° 10′	20° 00′	....
Limestone-gangue ores	19° 40′	17° 30′	30° to 40° for steel 45° for wood.
Sandstone-gangue ores	22° 30′	19° 40′	30° to 40° for steel 45° for wood.
Hematite (Lake iron ore)	22° 40′	20° 40′	30° to 40° for steel 45° for wood.
Missouri galena	19° 20′	17° 20′	30° to 40° for steel 45° for wood.

Standard lump	25–30*a*
Nut	26–37
Slack	30–45

a Chutes for lump coal range from 18 to 33° slope.

Size of grizzly depends upon the size of feed, percentage of undersize, slope and aperture. Width is governed by the same rule that governs width of chutes, *viz.:* the minimum width should be at least three times as great as the size of the largest particles in the feed, if the feed is fairly uniform in size, or twice as wide, if large lumps are rare. The width is usually governed, however, by other factors, such as chute width, width of car or skip supplying the feed, or width of crusher receiving opening. Length is determined by the amount of screening to be done, *i.e.*, if the aperture is small and the percentage of undersize large, more length must be provided than when reverse conditions obtain. Length of steep grizzlies should be greater than that of flat ones. No quantitative rules can be set down. Length is frequently made twice the width, but this relation has no logical foundation. If large particles slide along carrying fine material with them, they can be turned over by a drop in the grizzly surface or by dependent swinging bars, chains, ropes or the like placed about half-way along the length. These will, however, slow down the material and hence make it necessary to set the grizzly on a steeper slope than otherwise. Table 20 gives examples from practice. *Truscott* gives 12 to 15 ft. as usual lengths.

Average capacity may be taken as about 125 tons per sq. ft. of surface per 24 hr. with 1-in. opening and proportionately greater tonnages with greater apertures.

Holbrook and Fraser (*Bull. 234, USBM*) criticize this method of estimating the size necessary and give a rule of 500 tons run-of-mine coal per foot of width per 8 hr. without any statement of the aperture. This treats the grizzly simply as a chute.

Self-cleaning grizzly. Simcox and Humes (*117 J 307*) describe the grizzly illustrated in Fig. 11. The revolving arms prevent material from sticking between the bars. At

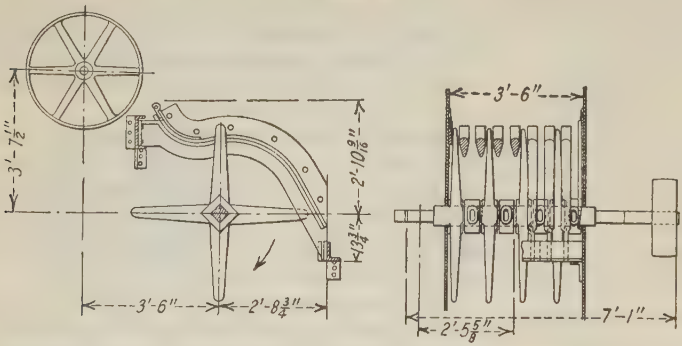

FIG. 11.—Self-cleaning grizzly.

COPPER QUEEN smelter this machine handled 196 tons per hr. of talcy ore containing 10 to 12 per cent. moisture which could not be handled by other types of grizzlies, and previously had been dried and re-handled at considerable expense.

ADVANTAGES of fixed grizzlies are simplicity and ruggedness. DISADVANTAGES are inefficiency, loss of head room, blinding, and, in the case of coal screening, breakage of oversize.

MOVING GRIZZLIES

Moving grizzlies of various types are used for the purpose of bettering screening, lessening breakage of material and saving head room. The first two purposes have determined their use in coal breakers, the second, in many ore-treatment plants.

Moving-bar grizzly (Fig. 12) is usual in coal breakers. Bars are mounted at one end on an eccentric, adjacent bars 180° apart, and are so driven that they move forward at the high position. Speed is about 50 r.p.m. The forward movement, together with a forward inclination of about 10° moves lump material gently along the grizzly and at the same time turns it over well and allows fines to drop through.

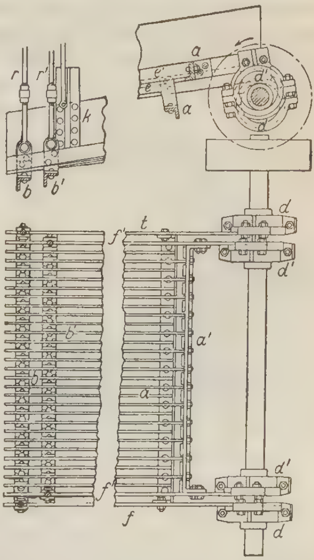

FIG. 12.—Briart moving-bar grizzly.

A chain grizzly was used between the tracks over the crude-ore bins at the ROWE MINE, Riverton, Minn. (*101 J 599*). It was built of old steam-shovel chains stretched endless over sprockets, the run of the chains being horizontal. Longitudinal rods in the plane of the upper chains were placed between the chains so that the

distance of a chain from a rod determined the aperture of the grizzly. Alternate chains were run at different speeds in order to break up lumps held together by clay and to prevent blinding. Oversize traveled on the chains to a chute feeding a primary crusher. The speed of the chains was 16 and 18 ft. per min. respectively, and it was possible to dump a 50-ton car directly onto the grizzly. Eleven supporting rollers were used between the head and tail rollers in a length of about 20 ft.

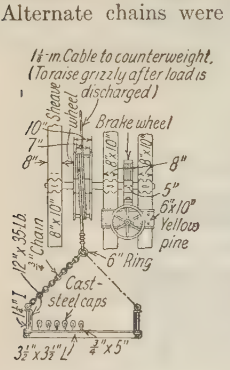

Fig. 13.—Movable sorting grizzly, Port Henry Iron Ore Co.

Movable sorting grizzly used at Port Henry Iron Ore Co. is shown in Fig. 13 (*88 J 884*). Its position is controlled by the band wheel. The counterweight is heavy enough to raise the empty grizzly to a horizontal position. The size is 6 ft. wide and 11 ft. long with 4-in. clear space between bars. The slope for discharging is 35°.

Traveling grizzly is shown in Fig. 14. It consists of short lengths of rail running across between two sprocket chains, the latter operating over head and tail sprockets, gear-driven. This grizzly is placed directly under a feed chute and is normally of adjustable speed to regulate feed to a crushing machine. Undersize passes through the upper run and is diverted both sides by chutes. Oversize is discharged over the head sprocket. Any material that tends to wedge between the bars is readily freed at the head sprocket because of spreading of the bars in passing around. Another form of this same grizzly is shown in Fig. 15(*a*). The drop of the bars on the lower run clears the surface and also allows the undersize chute to be placed below the return run. Fig. 15(*b*) shows the same type of grizzly used as a roller feeder. Speeds range, usually, between 10 and 20 ft. per min.

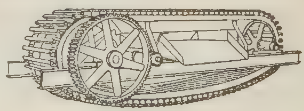

Fig. 14.—Traveling-bar grizzly.

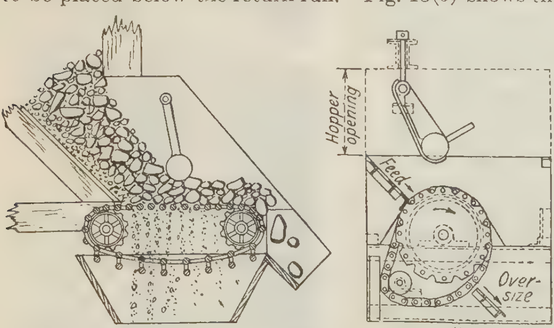

Fig. 15.—Drop-bar traveling grizzly.

Disk or roller type of grizzly consists of a series of disks properly spaced and mounted rigidly on a shaft; it replaces a roller feeder (see Sec. 19, Art. 4) at the discharge gate of a bin. The shaft is driven by a sprocket chain or by ratchet and pawl, oversize rides on the disks and passes to a crushing machine, while undersize drops through between the disks into a chute. The peripheral speed is dependent upon the rate of feed, but should not, in general, exceed 100 ft. per min.

Burchring grizzly (Fig. 16) is a special form of the roller type. It con-

sists of two disk-shaped heads (A) mounted on shaft (E) and tied together by rods (G) on which are mounted close-fitting rings (C), held in place by spacers (D), and alternate loose rings (B) spaced centrally between the rings (C) by the lugs (I). The principle lies in the fact that the loose rings always hang down in such a way that the space between adjacent rings at the bottom is greater than at the top and anything that passes between rings at the top is, therefore, readily discharged at the bottom.

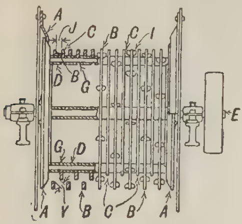

Fig. 16.—Burch ring grizzly.

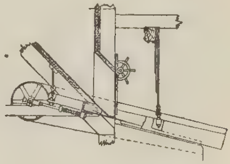

Fig. 17.—Shaking grizzly.

Shaking grizzly is shown in Fig. 17. It consists of grizzly bars carried in a suspended frame actuated by an eccentric. The surface of the bars is ordinarily inclined about 10° in the direction of flow, although this is not entirely necessary, if the method of suspension is that of the Ferraris screen. Speed should be about 80–100 strokes per min. Capacity is about 125 tons per sq. ft. per 24 hr. per in. of aperture.

At Empire Steel and Iron Co. (*99 J 560*) this type of grizzly with 2-in. spaces clogged badly and the bars were replaced by ¾-in. manganese steel plate with 2-in. round holes. This overcame the difficulty.

FIXED SCREENS

Fixed screens, as distinguished from fixed grizzlies, have an inclined screening surface consisting of punched plate or woven wire rather than of parallel bars. They size more closely than a grizzly on account of the fact that they limit the particle in two directions.

Holbrook and Frazer (*Bul. 234 USBM*) report that the undersize of a 1-in. grizzly yielded 24 per cent. on a 1-in. round-hole screen and that some of the material would not pass a 2-in. round hole.

Punched-plate screens may ordinarily be set on the same or a slightly steeper slope than a grizzly except that, when used for fine feeds, the slope must be greater on this account. Tables 21 and 22 show the effect of size of coal on sliding angles. Woven-wire cloth must be set on a considerably steeper slope (5° to 15°) than either bars or punched plate on account of the rougher surface. Capacity of fixed screens is 2 to 4 tons per sq. ft. per 24 hr. per mm. of aperture.

At Ohio Copper Co. (*99 J 749*) heavy wire screens, 2 ft. wide by 8 ft. long with 0.375 × 1-in. apertures, set on a 45° slope, handled 250 tons per 24 hr. or 1.1 tons per sq. ft. per 24 hr. per mm. At the old coarse-crushing plant of the Arthur mill of Utah Copper Co. (*117 P 715*) the 72 × 20-in. roll circuit was closed with stationary square-mesh woven-wire screens set at 40° slope, the aperture varying from 1 to 1.5 in. as the moisture varied from 5 to 13 per cent. In the new plant these screens have been replaced by Mitchell vibrating screens. At Alaska Gastineau (*63 A 493*) — 10-in. material was fed at the rate of 1000 tons per 8 hr. to a stationary woven-wire screen with 2.5-in. aperture, 3 ft. wide by 14 ft. long, set at 45° slope. This is 1.1 tons per sq. ft. per 24 hr. per mm.

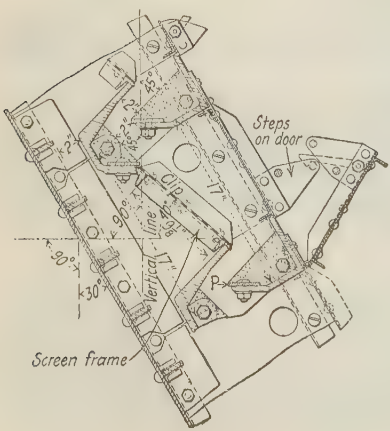

FIG. 18.—Rowand screen.

Screen with adjustable aperture is described by Watts (*40 CMJ 886*). It consists of a round-hole punched-plate fixed screen, the holes being punched with rectangular spacing, and a grizzly in contact with the under side of the plate, the grizzly bar being equal in width to the least width of metal between holes in the plate and the distance center to center of bars and holes being equal. When the centers of the bars register with the centers of the metal between holes in the plates the screen apertures are full open. By sliding the grizzly sideways the holes may be closed to any desired extent. This arrangement is useful on coarse screens when the moisture content of the feed is variable, but the same effect can probably be more easily obtained by changing screens.

Rowand screen (Fig. 18) is a modification of the old Edison screen (see *Richards*). Both screens

have been used to a considerable extent by the New Jersey Zinc Co. and subsidiaries for relatively fine screening of dry ores. The object of the apparatus is to feed ore in a thin regular stream over the whole screen surface and to break the flow of the ore a sufficient number of times to keep the velocity of the particles on the screen cloth low and to have them, therefore, slide rather than roll and bound. The essential elements in such screening are to have the feed substantially bone dry and to keep the aperture clear. Dryness both increases efficiency and markedly reduces wear on screening surfaces. Table 23 gives performances of Rowand screens. The

Table 23. Performance of Rowand screens, N. J. Zinc Co.

135	.025	43	11–13	11–13	2.1	3.3

average CAPACITY of the Rowand screen is 2 tons per sq. ft. per 24 hr. per mm. of aperture. The corresponding average of five Edison screens is 1.15 tons.

The ADVANTAGES of Rowand screens are lack of power consumption and low repair charges, due to absence of moving parts; the DISADVANTAGES are low capacity per square foot, excessive blinding, great loss of head room, and close dependence between efficiency and dryer performance. When the ore contains even so small an amount of moisture as to fail to allay dust, screen efficiency falls off badly and the circulating load builds up to enormous proportions. At NEW JERSEY ZINC Co. an alternating-current electromagnet mounted over a screen plate in a Rowand screen is locked electrically with a mechanism for regulating feed and with a timing arrangement, so that the feed is shut off for a few seconds every few minutes and the screen is vibrated vigorously. The result of the vibration is to clean the screen thoroughly. As a result capacity and efficiency have been greatly increased and a labor cost of upwards of $0.15 per ton screened for cleaning screens has been eliminated.

Drag screen is essentially a flight conveyor (Sec. 20, Art. 4) in a trough with perforated bottom. It may be set at any slope from a downward incline

less than the sliding angle of the material to a rise of the same inclination. The usual range in size is from 4 to 10 ft. wide and from 10 to 25 ft. long.

The usual CAPACITY of drag screens with ⅛- to $\frac{5}{16}$-in. round-hole plate is 1 ton per sq. ft. per hr.; the general limits are between 2 and 15 tons per sq. ft. per 24 hr. per mm. aperture. The usual speed is 60 to 100 ft. per min. but speeds from 40 to 240 ft. per min. are reported. Wear is not great with coal but is excessive with hard ore. The screen is used principally as a dewatering elevator or conveyor in coal washing, where screening is of secondary importance.

Lincoln (*11 Bul. UI, No. 9*) describes such a screen 2 ft. wide by 24 ft. long with 16 ft. of 1¾-in. slotted plate and 8 ft. of ⅜-in. square-hole plate which handled 40 tons per hr. of −3¾-in. raw coal. Another screen 3 ft. wide × 30 ft. long with 1½-in. grizzly bottom, sloped +26° for part of the run, then horizontal, handled 600 tons per 8 hr. at 80 ft. per min.

5. Revolving screens and trommels

Revolving screens have been more widely used than any other type of movable screen, but their popularity, particularly for screening finer than 1½- or 2-in., is on the wane at the present time. The ordinary cylindrical TROMMEL as used in ore-treatment plants is shown in Fig. 19. It consists essentially of a through-shaft carrying two or more 4- to 6-armed spiders, on the outer end of which are carried circular bands on which screen cloth is stretched. The main shaft is carried in bearings at the two ends. Several methods of drive are employed. The commonest is the so-called right-angle drive illustrated in the figure, consisting of a bevel gear mounted on the end of the trommel shaft and driven by a bevel pinion on the countershaft, which is, in turn, pulley-driven. A less common form of drive is one in which a pulley is carried directly on the end of the trommel shaft. Since the shaft of a cylindrical trommel is always on a slope, there is difficulty in keeping a belt on this pulley, especially as the trommel is a slow-speed machine. This difficulty is overcome, in some cases, by connecting the trommel shaft through a universal joint with a horizontal shaft in the same vertical plane and driving this directly by means of a pulley. Sprocket and chain may be substituted for belt and pulley in the last two drives and sprocket and chain are frequently used with the right-angle drive in dry screening, where the excessive dust would cause belt trouble. Common diameters are 24, 30, 36, 42, 48 and 60 in.; lengths, 4 to 12 ft.

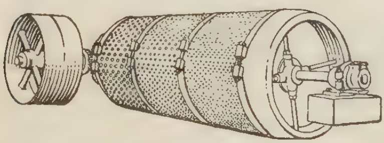

FIG. 19.—Cylindrical trommel.

Split spider hubs are superior to solid. The shaft for a 24 × 72-in. trommel should be $2\frac{11}{16}$-in., increasing to about $4\frac{7}{16}$-in. for the 48 × 72-in. size. For longer screens the shaft diameter must be increased considerably. The driving shaft should be fitted with a tight-and-loose pulley. The minimum slope of the undersize chute for wet work should be at least 2¾ in. per ft. for 2-mm. screen. The chute should slope at least 45° for dry screening. Wash-water boxes are better than spray pipes unless the water is clean and free from salts. Water should be applied on the upcoming side. Water consumption varies from 1 to 3.5 gal. per min. per ft. of length, the higher figures generally corresponding to fine screening. Water consumption in terms of tonnage of solid fed to the screen varies from 18 gal. per ton in coarse screening to 420 per ton in 1-mm. screening.

Wiard states that power consumption is about ¼ hp. per 2-ft. length for 48-in. trommels. Holbrook and Fraser give the formula $Hp. = tons\ per\ hr./10$; also $Hp. = DL/8$ where D and L are diameter and length in feet, respectively, for coal-screening trommel,

and $Hp. = DL/4$ for stone screens working on rock or ore. For light shaft-type trommels for fine screening in concentrating mills they give $Hp. = DL/12$.

Trommels for wet screening may be set up in banks of two to four in line, with intermediate spur-gear drive, but individual drive is better.

Compound trommels with two or more concentric screening surfaces on the same shaft, the coarsest inside, are used where several sizes are desired in the same screening operation and head room is at a premium.

The DISADVANTAGES are that it is necessary to remove the outer screens in order to make repairs on the inner, it is difficult to watch the inner screens for wear and blinding, and the area of the expensive fine-screen cloth is unnecessarily great.

Revolving stone screens, as distinguished from trommels, have no central shaft but are mounted on tires and rollers at both ends, or one end is so mounted and the other end carries a heavy head and gudgeon (Fig. 20, *b*). This type of screen is used for coarse screening only and is less frequently used in ore-treatment plants than in stone-crushing plants. The screen frame consists of heavy cast heads with four or more longitudinal members connecting

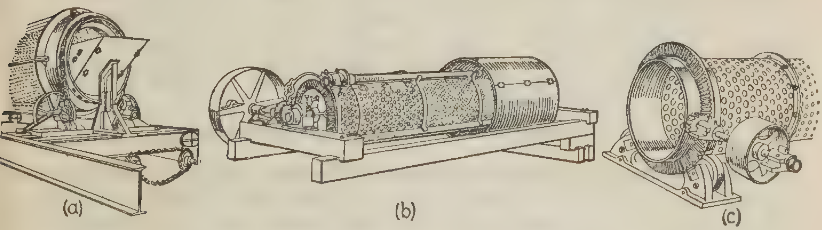

FIG. 20.—Revolving stone screens.

the heads and forming with them a strong truss. The screening surface is attached to the through members. The best arrangement is one in which the screens are in sections, each section bolted in between two adjacent through members as shown in Fig. 20, *b*. Commonly stone screens are SECTIONAL (Fig. 20, *b*), *i.e.*, plate or cloth sections of successively coarser aperture from feed to discharge end are used. Not infrequently, also, they are compound at one end. Right-angle drive is usual, but some forms are chain-driven by means of a sprocket bolted to the feed- or discharge-end casting (Fig. 20, *a*). The frame is sometimes built to carry a grid of heavy rods on the inside surface, parallel to the axis, with an aperture larger than the coarsest screen. This rides the largest lumps through the screen out of contact with the screening surface and thus protects the latter. Table 24 gives sizes and weights throughout the range of manufacture.

The principal DISADVANTAGE of this type of screen is the fact that all of the coarse material must pass over the finest plate, which is thereby subjected to excessive wear. This difficulty may be obviated, although at the expense of head room, by passing the original feed first to a heavy screen of intermediate size and passing each product of this screen to a separate sectional screen having suitable cloth.

Conical trommels are made with and without a through shaft. The latter type, called the Gilbert screen, has had considerable use, particularly in gravel-washing plants.

The ADVANTAGE of the conical trommel is that the axis is set horizontally and the inclination of the screening surface necessary to cause travel of material is obtained by the conical

shape. It is also economical of head room. The open-end type has ample space for feeding through the discharge end, but it is necessary that the feed be carried in suspension in water.

Table 24. Revolving stone screens. (*Traylor Engineering Co.*)

a As guard screen on a crusher. *b* For clean oversize.

Prismatic trommels, usually hexagonal, have been used to a considerable extent in fine screening. The sides may have their elements parallel, in which case the axis is set on a slope, or the sides may be pyramidal and the axis set horizontal. The screening surface consists of a number of plane sections. This makes for ease in mounting and changing screen cloth, as the cloth is mounted on separate wooden frames that bolt onto the main screen frame. Cloth may be shipped flat, is lighter to handle than that for a cylindrical trommel, being in smaller pieces; and the amount of screening surface that need be replaced for a break in the screen is only one-sixth of the total.

Comparison of round and hexagonal trommels for fine screening was made at the mill of the Desloge Consolidated Lead Co., South-eastern Missouri (*94 J 833*). The material to be screened was undersize of a 10-mm. trommel and it was desired to remove from it material that would pass a 1-mm. opening. Comparison was between a round trommel of the conical type, 8 ft. long with diameters 3 and 4 ft., slope ¾ in. to the foot, speed 20 r.p.m.; and a hexagonal trommel 8 ft. long, pyramidal shape, largest diameter 4 ft., smallest diameter, 3 ft., speed, 20 r.p.m. Pulp in falling from one face of the hexagon to the other dropped 14 in. Screening surface used on both trommels was punched plate, 22-gage steel, 1-mm. round holes on 2.5-mm. centers. Outside spray was used in both cases. Feed rate, both trommels, was 150 tons per 24 hr. Duration of the test was several weeks. Results were as follows: Material finer than 1-mm. in oversize; conical trommel, 7.02 per cent; hexagonal trommel, 4.77 per cent. Life of screening surface; conical trommel, 7.1 days, 1065 tons; hexagonal trommel 12.85 days, 1927 tons. The experimenter calls attention to the fact that the difference in life of screening surfaces is due to the fact that the interior rings of the conical trommel cause pulp to back up behind them and that the greater weight of pulp sliding around at these points causes the screens to wear through there and fail. The higher efficiency of the hexagonal trommel was due to greater turning over of pulp and consequent more frequent presentation of all grains to the screening surface.

Variables in construction and operation of revolving screens are speed, slope of screen axis, aperture, percentage of oversize in feed, percentage of moisture in feed, quantity of feed per unit of time, diameter, length and character of screening surface.

Speed affects capacity and efficiency. Increase in speed up to the point where material is carried completely around by centrifugal force causes increase in capacity. Efficiency, however, passes through a maximum with increased speed.

Results of a test on a 36-in. trommel with varying speed (*98 J 305*) are given in Table 25 and Fig. 21, showing, for this size, maximum efficiency at 16 r.p.m. Since efficiency and not capacity is the end sought in most screening operations, this speed or one slightly greater, is the one that should be and is commonly used in practice for this size of trommel.

Diameter, 36 in. Length, 12 ft. Slope, 1¼ in. per foot. Perforations, ½-in. round holes, punched on lines intersecting at 60°. Percentage of opening, 40.3. Rate of feed, 22 to 24 tons per hour. Speed, 11 to 22 r.p.m. (Data plotted in Fig. 21.)

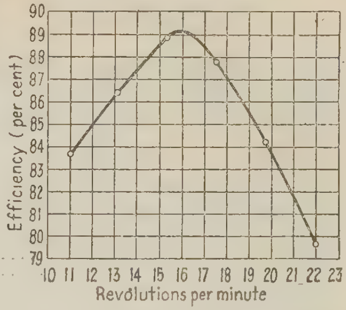

Fig. 21.—Relation of trommel speed and efficiency. (Numerical data in Table 25.)

Table 26 shows speeds of operating trommels in various mills. Average speeds are as follows: 2-ft., 17 r.p.m. (2 only); 2.5-ft., 16.4 r.p.m. (5 only); 3-ft., 16.75 r.p.m. (4 only); 3.5-ft., 15.5 r.p.m. (2 only); 4 ft., 15 r.p.m. (10 only); 4.5-ft., 15 r.p.m. (1 only). Table 27 shows the theoretical speed producing centrifugal cling and the usual speeds for ore and for coal screening, according to Holbrook and Fraser (*Bul. 234, USBM*).

Efficiency, per cent.	79.6	84.2	87.8	88.9	86.4	83.7

Slope of a trommel affects the speed of passage of material therethrough, and for a given tonnage determines the thickness of the bed on the screen. This factor in turn influences efficiency, the thinner the bed the greater the opportunity for material to have access to an aperture. Up to the point where the rate of travel of particles over the screening surface is too great for efficiency, increase in slope increases efficiency and capacity. The old practice was to use slopes of 0.5 to 0.75 in. per ft. Present practice, as indicated by Table 26, averages about 1.5 in. per ft. in ore treatment. The maximum is about 3 in. per ft. According to Holbrook and Fraser, 5° is standard slope for punched plate-trommels in coal treatment and slightly more for woven-wire.

Diameter of a trommel determines the thickness of the bed; the greater the diameter the thinner the bed. It is not advisable to use trommels less than 36 in. diameter on account of the difficulty of changing screens and making other repairs. The majority of trommels range from 36 to 48 in. diameter.

36	56	20 to 30	189 to 283	23 to 26	217 to 245
48	48	12 to 22	151 to 277	19 to 20	239 to 252
60	43	11 to 13½	173 to 212	15 to 16	236 to 252
72	40	11 to 13	207 to 245	12 to 13	226 to 245
84	35	10 to 11½	220 to 253	8 to 11	176 to 242

Length affects efficiency of screening; increased length resulting in more complete removal of fines. On the other hand, most of the screening is done in the first 2 feet. Present practice inclines to steep slopes and short lengths. *Truscott* gives 5 to 15 ft. for one separation, the longer for finer materials, but few trommels exceed 10 ft.

Capacity increases with increase in diameter, speed, slope and size of aperture, with decrease in percentage of difficult oversize in the feed, and is greater in wet than in dry screening. On the basis of Table 26 capacity is 0.6 ton per sq. ft. per 24 hr. per mm. of aperture for dry screening and 1.0 ton per sq. ft. per 24 hr. per mm. for wet screening. *Wiard* gives the rule for capacity of 48-in. trommels in open circuit, $C = 20\,d$ for round-hole punched plate and $C = 25\,d$ for square openings, where C = tons per 24 hr., d is the aperture in mm., and the feed contains 50 per cent. oversize. With a greater percentage of oversize, capacity will be greater to an extent substantially equal to the tonnage of excess above 50 per cent. oversize. Deduct 15 per cent. from the above capacities for each 6-in. decrease in trommel diameter. *Truscott's* figure is 0.5 ton per 24 hr. per sq. ft. per mm. Holbrook and Fraser give the rule for capacity on coal that 3 to 4 sq. ft. of screen surface is required per ton per hour per inch of aperture, with an increase of 50 per cent. in the area required if the coal is damp. Lincoln (*11 Bul. UI, No. 9*) gives data concerning the performance of a considerable number of revolving screens working in Illinois bituminous-coal washeries. Average capacity (19 screens) in sizing raw coal, 1-in. to 3-in. maximum size, over round-hole plate with ¾-in. to 2¾-in. openings was 0.36 ton per sq. ft. per 24 hr. per mm. of aperture and the range was from 0.05 to 1.20 tons. When re-sizing washed coal that had been sized prior to washing, the feed ranging from 3-in. down to ¾-in. maximum size and the screen apertures from 2½- to ¼-in. round-hole, the average capacity (41 screens) was again 0.36 ton per sq. ft. per 24 hr. per mm. and the range from 0.04 to 2.00 tons. In sizing washed coal, the feeds ranging from 3½- to ⅜-in. maximum, and the screen apertures from 2- to ¼-in. round-hole, the average capacity (29 screens) was 0.66 ton per sq. ft. per 24 hr. per mm. and the range from 0.12 to 2.80 tons. In draining or rinsing washed coal on 1⁄16- and 3⁄32-in. screens, capacities were 4.30 to 5.30 tons per sq. ft. per 24 hr. per mm.

Efficiency. Averages from Table 26 show that the oversize from coarse (plus-0.5-in.) dry trommels contains about 15 per cent. undersize, while that from fine (minus-0.25-in.) wet trommels contains about 30 per cent.

Efficiency reckoned as percentage recovery of undersize may run as high as 80 per cent. in ½-in. dry trommels. In wet trommels 45 to 70 per cent. is the usual range, but the figure may drop to 10 per cent. or lower when there is much material in the feed near the size of the screen opening, and the trommel is overloaded.

Table 28. Life of punched plate on trommel screening hard quartz ore. (*After Forbes*)

Diameter of holes, inches	Thickness of plate	Tons screened
⅝	5/16 in.	21,000
⅜	¼ in.	21,000
3/16	10 gage	18,860
1.5 mm.	16 gage	5,850

Life of covering on trommels is given in Table 26. Forbes (*43 A 487*) gives the data in Table 28.

Advantages of trommels are simplicity in construction and operation, freedom from vibration, small loss of head room and general ruggedness. Disadvantages are blinding, difficulty of repair, low capacity per square foot of screen surface and low efficiency.

Bunker Hill screen, developed and used at Bunker Hill and Sullivan Mining Co., is a variety of revolving screen in which a conical screening surface is made to revolve around an axis inclined 45°. (See Fig. 22.) It is for fine screening only and has not been used extensively. The screening surface is carried on a light framework attached to a trunnion, which revolves in an inclined bearing, revolution being accomplished by means of a bevel gear, bevel pinion and pulley. Feed is introduced through a box set to deliver pulp tangentially to the screen surface near the top of the down-coming side. Undersize collects in the conical housing and passes out through the chute shown, while oversize passes to the apex and out through a hollow trunnion. Water sprays are provided as shown, the interior one adjustable. Average speed is 20 r.p.m. Capacity, with different sizes of screen cloth is, according to the manufacturer, as given in Table 29.

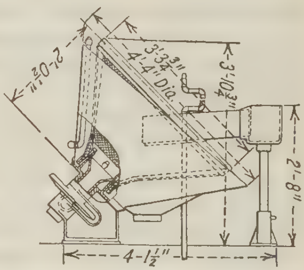

Fig. 22.—Bunker Hill screen.

Table 29. Average capacity of Bunker Hill screen. (*Hendric and Bolthoff*)

Mesh	Working load, tons per 24 hr.
6	150
16	100
22	55
30	40
Finer than 30-mesh	Up to 30

At Bunker Hill and Sullivan (*3 MM 45*) a screen with 22-mesh cloth handled 50 to 80 tons per 24 hr. of −2-mm. feed, or 4.5 to 7.2 tons per sq. ft. per 24 hr. per mm. The volume of feed should be kept down to 150 gal. per min. at 6-mesh, 100 at 22-mesh and 80 at finer meshes. Life of 22-mesh steel-wire screen at Bunker Hill and Sullivan was 13 days. Oversize contained 10 per cent. undersize.

6. Shaking screens

Description. Shaking screens consist essentially of a shallow rectangular box two to four times, or more, as long as wide, open at one end, fitted with a screen bottom and shaken by means of a suitable mechanism which alone, or in conjunction with the slope of the screen surface, moves oversize to the discharge end. The method of support of the frame and the means of shaking vary considerably. In the oldest and simplest form the frame is supported on four vertical rods or chains at the corners and actuated by an ordinary

eccentric. The motion under such circumstances is substantially straight-line harmonic motion and the screening surface must be given a slope of 10 to 15° in order to move material, or the forward stroke must be ended against a bumping block. The use of bumping blocks produces excessive rack and vibration on the screen frame and supports. By inclining the supporting rods backward from the vertical at an angle of about 15° (Ferraris support), the motion of the screen surface is upward at the end of the forward stroke and sharply downward at the beginning of the backward stroke, with the result that the screen drops away from under the load and the material moves ahead with a series of jumps. This motion is accented by shortening the suspending rods. The same effect, even more sharply accented, can be obtained by mounting the screen frame on rollers and shaping the track to give a sharp upward movement at the end of the forward stroke. Occasionally, with track support, the track is also turned up at the end of the backward stroke, in order to give some backward travel of the material and thus increase the length of path and multiply opportunites for undersize to pass. Table head motions, which impart a differential, quick-return movement, are suitable only for relatively short strokes (1.5 in. or less) and relatively small screens. With mechanisms producing differential movement the screen surface need be inclined only slightly or not at all in the direction of flow.

Speed, slope and length of stroke should be adjusted to produce rapid stratification of the feed, quick forward movement of the load and minimum blinding. If speed or length of stroke is too great, material is thrown bodily away from the screen surface and stratification is effected slowly, if at all. On the other hand, if there is too little throw, the screen blinds badly. Slope is adjusted so that with a proper speed and length of stroke there is sufficient throw of material away from the screen surface to prevent blinding. Speeds in practice range from about 60 or 70 @ 9-in. strokes per min. to about 400 @ ¾-in. strokes. The average for coal shakers is about 100 @ 6-in. strokes per min. A common rule for design of shaking coal screens is to make the product of stroke length in inches by strokes per minute equal 600 and to slope the screens about 14° for coarse coal and 18 to 20° for fine. Holbrook and Fraser state that these slopes should be reversed on account of the greater impulses, normal to the screen surface, required to clear coarse perforations. Assuming that the load moves forward with the screen but has no backward movement the general rule above gives the coal a forward velocity of 50 ft. per min. and some designers thus state the rule (*2 CA 352*).

If there is any considerable amount of lost motion or back-lash in the eccentric or suspending mechanism the action of material on the screen may be entirely different from that with the same mechanism with no back-lash. Suspending rods made of ash boards, 1- by 10- or 12-in. in section, attached rigidly at both ends are very durable and have a tendency to reduce back-lash. Table 30 gives data on shaking screens in various concentrating mills.

Capacity ranges from 2 to 8 tons per sq. ft. per 24 hr. per mm. of aperture. In de-sanding pebble phosphate 15 to 20 tons per sq. ft. per 24 hr. per mm. is sent over $\frac{3}{64}$-in. screens in a 3-in. bed with 400 to 500 gal. per min. of wash water, but the screening is not efficient. Wiard (*Liddell*) gives a formula that reduces to $T = AR/6P$ as a maximum theoretical tonnage for shaking screens where T = capacity in tons per hr. per ft. of width; A = average between screen aperture and preceding limiting-screen aperture, expressed in feet; R = rate of advance of material over the screen in inches per min. = shakes per min. × amplitude of shake; and P = ratio of weight of oversize to total

feed. This formula gives results lower than those shown in Table 30. In screening bituminous coal, capacity is usually considered to be a function of width only. Holbrook and Fraser (*Bul. 234, USBM*) give Table 31 as representative of common practice. The 1.5- to 2-in. slack screen is the minimum aperture. These writers also give a table used by certain designers of coal tipples which shows an allowance of 1 sq. ft. per ton per 24 hr. per mm. of aperture for screens handling 125 tons per hr., but for four times this capacity the area allowed is less than twice as much. Another table covering practice at 43 Central Interior mines (bituminous) shows 2 tons per sq. ft. per 24 hr. per mm. for slack screens at small mines (less than 1000 tons per 8 hr.) to 5 tons per sq. ft. per 24 hr. per mm. at mines handling upward of 4000 tons per 8 hr. The writers ascribe the higher tonnages handled per sq. ft. on the large screens at the large mines to uniform, well-distributed feed and the use of a coarse relief screen above the slack screen. Lincoln (*11 Bul. UI, No. 9*) gives data on a number of shaking-screen installations in Illinois coal washeries. The average capacity in tons per sq. ft. per 24 hr. per mm. of aperture for 23 screens with round-hole punched plate, ranging from ¼-in. to 2¼-in. openings, was 1.1, with an extreme range from 0.04 to 3.1 tons. For screens in dewatering service, with $\frac{1}{16}$- and ⅛-in. round-hole punched plate, capacity was from 8.4 to 10.1 tons per sq. ft. per 24 hr. per mm. Roberts and Schaeffer (*PC*) recommend 30 to 50 tons per hr. per ft. of width for picking and 50 to 75 tons for slack screens. Anthracite shakers are run at higher speed and with shorter stroke than bituminous shakers. Table 32 made up from Ashmead's description of the Susquehanna Collieries Co. (*66 A 422*) shows a much larger feed rate

per sq. ft. per 24 hr. mm. for the fine screening than for the coarse. This is partly due to the fact that specifications for fine sizes of anthracite are much less rigid than for the coarser sizes and partly due also to the fact that the coarser screens are under-loaded while the finer are overloaded. Areas of shaking screens in Dunmore breaker of Pennsylvania Coal Co. (*22 CA 785*) for 4000 tons per 8 hr. are: Lump size, 90 sq. ft.; grate size, 225 sq. ft.; egg, 609 sq. ft.; stove, 360 sq. ft.; chestnut, 648 sq. ft.; pea, 180 sq. ft.; No. 1 buckwheat, 180 sq. ft.; rice coal, 216 sq. ft.; barley, 216 sq. ft. Table 33 (*22 CA 5*) shows the areas of the shakers in another anthracite breaker, with the tonnages of feed and oversize handled.

Table 31. Width of screen for different tonnages of run-of-mine bituminous coal

Rice	$\frac{1}{4} \times \frac{7}{16}$	2.15
Barley	$\frac{3}{32} \times \frac{1}{4}$	5.00

Power consumption for screens handling coal averages from 0.04 to 0.05 hp. per sq. ft. of screen surface when the screen is run at average speed and with average load. Installed horsepower is 1.5 to 2 times the average consumption. Screens handling ore are ordinarily run at a much shorter stroke so that the screen travel in feet per minute is only about half of that of coal shakers, but the load per square foot is much heavier. From the meager data in Table 30 it would appear that power consumption is between 0.08 and 0.11 hp. per sq. ft. of screen surface.

Table 33. Areas of shaking screens at Seneca breaker of Lehigh Valley Coal Co.

Screen banks making several different products are arranged either with the different screens in the same plane with all feed going over the finest screen, or with superimposed boxes driven by the same mechanism, with the coarsest screen in the uppermost box. In either case speed and amplitude must be a

compromise and since long slow stroke is necessary to move the coarse material, fine screening suffers.

Applicability. Shaking screens are used to the greatest extent in coal dressing, where they have substantially displaced all other types, and in treating certain non-metallic ores such as those of phosphate and asbestos. They are used both wet and dry, but consume excessive amounts of spray water when used wet. Many attempts have been made to set the screen so that it moves up and down through the surface of a body of water, but this involves mechanical removal of undersize, which has not proved successful. Shaking screens are not suitable for treating clayey ores on account of the readiness with which clay balls form on them. Their suitability for coal washing is based upon the fact that they load and discharge with but little vertical drop and do not subject the coal to much tumbling action during screening, hence there is but little breakage. Another advantage is that by extending a screen over three or four loading tracks, slack may be loaded into a car on the track nearest the feed end and progressively coarser sizes into cars on succeeding tracks. Blank plates cover the space between tracks. Thus mounted, the screen is both a sizing device and a loading conveyor and is frequently so used in bituminous-coal tipples.

The principal DISADVANTAGE of shaking screens is the high repair cost due to rack and vibration. This applies not only to the screen itself but to the supporting structure. In order to minimize the effect on the structure two screens are frequently mounted on opposite sides of the same drive shaft with eccentrics at 180°. Even this is insufficient, however, to balance the load because of the difference to be expected in load of material on the two screens at any given instant, hence many designers make the shaking-screen support independent of the building frame, in order to localize vibration and not rack the entire building.

Anti-gravity screen is a shaking screen with a deck about 3 ft. wide by 7 to 8 ft. long, fed at the mechanism end and sloping upward toward the discharge end at an angle of about 12° with the horizontal. Under the screen deck is a blank deck, which slopes upward toward the discharge end at an angle of about 7°. The decks are about 12 in. apart at the discharge end. Forward travel is attained by supporting the shaking frame on sloping cast-iron sliders, so that the deck falls away from under the materials on the backward stroke. The screen is run at 350 @ 1-in. strokes per min. Capacity at this speed at St. Louis, Rocky Mtn. and Pacific Co. plant at Raton, N. M. (*23 CA 791*) was 30 tons per hr. of − 1-in. feed over a battery of 5 screens in series, with ¾-in. and ½-in. square-mesh wire and ⅜-in., 3/16-in. and 1/16-in. Ton-cap screens respectively. At 300 strokes per min. the capacity was too low.

7. Vibrating screens

General. Vibrating screens developed from shaking screens in an attempt to overcome the blinding that the latter suffer when screening fine dry material. They differ from shaking screens in that the motion imparted to the screening surface is rapid, vigorous movement of small amplitude in a direction substantially at right-angles to the screening surface. Ordinarily the rate of vibration is very much greater than that of even the most rapid shakers. The early forms produced vibration by hammering the screen surface, either directly or through small anvil blocks fastened thereto, but in such mechanisms vibration was of low speed and decidedly localized. The next step in development was vibration of the screen frame as a whole. Several forms of pulsing, waving and vibrating screens were built on this principle. The Colorado impact screen was the most successful of these early types. The final development was attachment of the vibrating element of a high-speed

vibrator directly to the screen surface, usually near the center. Of this type, the Mitchell, Hum-mer and Leahy are the best known.

b Recovery of undersize. *W* Steel-wire cloth. *y* Revolutions per minute of pulley.

Colorado impact screen is shown in Fig. 23. It consists essentially of the wooden frame (A) which carries the screen cloth and an undersize hopper (E), mounted on two elliptical wagon springs (B) which are fastened to the supporting frame. A shaft carrying multiple-armed cams (D) and pulley-driven is also mounted on the supporting framework. Revolution of the cam depresses the screen frame, which, on release, springs forward against bumping blocks on the framework. The usual speed is about 600 knocks per min. The screen surface is set at a slope of about 40° from the horizontal. The screen is made in two sizes, *viz.*: 3 ft. wide by 3 ft. long and 3 ft. wide by 4 ft. long. Screens may be superimposed, as shown in Fig. 23. Table 34 gives data concerning installations in several mills. It indicates an average capacity per square foot of screen surface per 24 hr. at 1-mm. aperture of about 5.5 tons for dry screening and about 20 tons for wet screening. An efficiency test on impact screens at Ray Cons. Copper Co. is shown in Table 35.

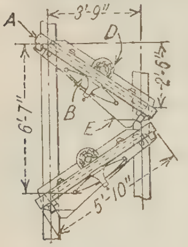

Fig. 23.—Colorado impact screen.

a Original mill feed, open circuit. b Original mill feed, plus oversize from rolls c One test. d Recovery of undersize.

Mitchell screen (Fig. 24) consists essentially of the screen (a), stretched to drum-head tightness by means of tension rods (b), suspended by side plates (c) from the ends of the vibrator (d), which, in turn, is supported at the center only in cradle (e) from the main frame. Detail of the vibrator is shown in Fig. 25. It consists of a motor (A), in a dust-proof frame. Two ball cages (D) carried on the ends of the motor shaft revolve inside the cylindrical ball races (E). One set of balls only is placed in each ball cage and these sets are spaced at 180° on the shaft, as shown. When the motor shaft is revolved, the unbalanced load of the balls against the races combined with the gyroscopic action of the rotor causes each element of the motor housing to generate the surface of an acute double cone with common apex in the vertical plane through the center of the suspending cradle. This motion is transmitted through the side plates (c) (Fig. 24) to the screening surface. The motor speed is about 3400 to 3600 r.p.m., producing the same number of vibrations. Intensity of vibration is varied by changing

a Feed – 1.5-in. grizzly. *b* Feed mixed nut and slack.

the size or number of balls in the ball cage. Power consumption is from 3/8 to 1/2 hp. for a 4 × 6-ft. screen. Slope of the screening surface is about 35 to 40° and may be varied while the screen is in operation. The path of the cross wires of the screen under the influence of the vibrator is circular, the direction of rotation being determined by the direction of rotation of the rotor. When the direction of the vibration of the wires is such that the movement at the top of the path is up-slope so that the wires are driven into the mass of downcoming material, maximum efficiency is obtained. Capacity on ores is about 11 tons per sq. ft. per 24 hr. per mm. of aperture.

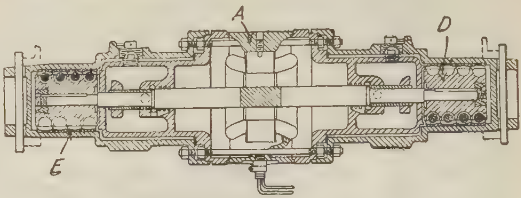

Fig. 25.—Vibrator of Mitchell screen.

Table 36 gives some tests on coke and bituminous coal. The tests on 0.25-in. screen show that the capacity on both coke and coal is about 8 tons per 24 hr. per sq. ft. per mm. The screen is clearly underloaded with the coarser cloth. The tests show also that, as the percentage of undersize in the feed increases, the tonnage that can be passed per millimeter of opening likewise increases. The tests with 0.25-in. coke indicate that a slope between 30° and 39° is better than a smaller slope. The effect of excessive moisture on screening is emphasized by the first test with bituminous coal. The experimenters noted that 50 to 60 per cent. of the holes in the screen were blinded by fine coal during this run. A given percentage of moisture is not so harmful with coke as with bituminous coal, due, no doubt, to the fact that much of the water is in the pores of the coke, and therefore has no effect on the behavior of the coke surface while much of the moisture in the coal is at the particle surfaces.

Hum-mer screen is a high-speed vibrating screen in which vibration is attained by means of a solenoid-buzzer mechanism with the moving part attached to the screen cloth. A diagrammatic sketch of the vibrator is shown in Fig. 26; (*c*) is the electro magnet, (*h*) the armature, to which is attached the post (*i*), which in turn, is attached through the foot (*j*) to the screen cloth. The amplitude of vibration may be varied by depressing the armature by means of the hand wheel (*a*). The upward motion of the screen terminates suddenly when the armature hits the striking block (*e*). The vibrating mechanism requires 15-cycle alternating current, hence ordinarily a special generator. A 1-hp. motor will drive a generator to furnish current to two vibrators. The usual size of a unit screening surface for ores and the like is 3 ft. wide by 5 ft. long, for coal 4 ft. wide by 5 or 7 ft. long. The 7-ft. length is sometimes built with two vibrators, an extra-powerful one to vibrate the upper 2½ ft. Screen tension is varied by means of tension rods. Both tension and amplitude adjustments may be made while the screen is in operation. Performance is materially affected by these changes. Vibration should be such that the material is lively, yet hugs the screen surface and travels rapidly.

b Recovery of undersize. *c* Feed all through ¾-in. *g* 108 tons of new feed per hour to 0.0445-in. (16-mesh) scalper screen, undersizes in order to successively finer screens. *h* 2-hp. motor runs generator for vibrators. *i* About 0.5 hp. for screw-conveyor feeder. *j* See Table 38*b*. *k* 16-mesh, 135 da.; 40-mesh, 104 da.; 60-mesh, 107 da.; 100-mesh, 88 da. *l* 10-mesh screen has lasted 300 days. Screens usually break before wearing out. *m* Mixture of pyrolusite and psilomelane. *n* Upper screen. All screens underloaded. *o* Screen has large excess capacity. *p* Feed all −2-in. *q* See Table 38*a*. *r* At 0.75-in. *s* Heavy vibrator. *t* Light vibrator. *u* About 39½ tons per hour passes the screen in both of the Calumet and Arizona screens, but the second is in closed circuit, so that there is a larger percentage of "difficult grains," and it has a light, instead of a heavy vibrator. *w* Steel-wire cloth. *x* To get 0.185-in. product.

Bland (*107 J 1114*) states that in some tests with a screen having 24-mesh cloth (0.0287-in. opening) at 32° slope, the oversize contained 34 per cent. − 30-mesh (0.0230-in.) material when the cloth was vibrated heavily and 6 per cent. with light vibration. When the screen was inclined 20°, the corresponding figures were 26 per cent. and 3 per cent., yet sand remained on the screen longer at the lower slope with heavy vibration than at the higher slope with light vibration. He presents Table 37 as giving best conditions of slope, vibration, screen length and capacity for screening dry and damp quartz sand.

−200	5.5	0	0.4	6.5	27.5

Capacity on ores is 10 to 15 tons per sq. ft. per 24 hr. per. mm. of aperture. The capacity is much higher, up to 20 tons per sq. ft. per 24 hr. per mm., in gravel screening, where lower efficiency is acceptable.

Crowfoot (*69 A 176*) states that in the design for the new Phelps-Dodge mill at Morenci, Ariz., 1 sq. ft. of 6-mesh screen surface was allowed for each 1.5 tons of 6-mesh undersize per hour. Table 39 gives results of a test on a mixture of nut and slack bituminous coal,

preparing for subsequent concentration. Holbrook and Fraser report 18 to 20 tons per sq. ft. per 24 hr. per mm. screening raw bituminous coal over 3/16-in. cloth, and 10 tons per sq. ft. per 24 hr. per mm. screening anthracite culm on 8-mesh rectangular-weave cloth.

A W. S. Tyler Co. representative says (*25 CA 762*) that an 8 × 5-ft. Hum-mer screen with 3/16-in. apertures will handle 100 to 120 tons of bituminous coal per hour and that two 4 × 5-ft. screens in tandem screened 180 tons per hr. making −¾-in. undersize, using 1⅛-in. square-mesh cloth, with heavy vibration on the first unit and light on the second. The oversize contained 9 per cent. undersize (¾-in. round hole) of which 7 per cent. was +½-in. The undersize contained 4 to 4½ per cent. on ¾-in. round hole.

When screening coal with 12 per cent. moisture, the oversize on ¼-in. contained about 8 per cent. undersize; on ⅛-in., 20 per cent.; on 1/16-in. over 50 per cent. (Arms, *70A 772*.)

At West Canadian Collieries, Ltd., (*MCJ*, Jan., 1926) the capacities of Hum-mer screens used for preparing coal for dry cleaning were as in Table 40.

Table 40. Hum-mer screens on bituminous coal at West Canadian Collieries, Ltd. (*After Vissac*)

Screen, aperture, inch	Number of screens	Width of screens, feet	Tons per hour		
			Feed	Oversize	Undersize
¾	1	4	148	38	110
7/16	1	4	110	30	80
¼	2	8	80	24	56
⅛	1	8	56	18	38

Delameter (*22 CA 752*) states that a 6-ft. screen with 30 sq. ft. of screening area handled 80 to 110 tons of bituminous coal per hour on a screen with the equivalent of −3/16-in. clear square opening, with a consumption of 1 hp. The maximum permissible percentage of moisture for good screening is 10 per cent.

Leahy screen is one of the high-tension small-amplitude type, with a mechanical vibrator. The elements are a rectangular frame 3 or 4 ft. wide and 5 or 6 ft. long, with the lower cross bar adjustable endways by means of two tension bolts; a piece of screen cloth mounted on two cross bars and stretched tightly by means of the tension bolts above mentioned and two others at the upper end as shown; and a vibrating mechanism mounted cen-

trally on a bridge between the side bars. Details of the vibrating mechanism are shown in Fig. 27. It consists essentially of a multi-armed cam (*a*) of short lift, mounted on a pulley-driven shaft (*b*), which operates a tappet (*c*) and this actuates a tappet- or connecting-rod (*d*), the lower end of which is attached to a strap bolted to the screen frame. Sharpness of vibration is controlled by the coil spring (*e*), the tension of which is adjusted by nut (*f*). The usual maximum amplitude of vibration is 1/16 in. along a transverse line directly beneath the vibrator. The usual speed is 200 r.p.m., giving 1600 vibrations per min. The construction of the mechanism is such that the upstroke ends suddenly and the down stroke starts at maximum velocity, which tends to keep the meshes clear and imparts maximum liveliness to the load. The slope should be between 28 and 35°. Power requirement is between ¼ and ¾ hp. The weight of the 3 × 6-ft. size complete is 850 lb.

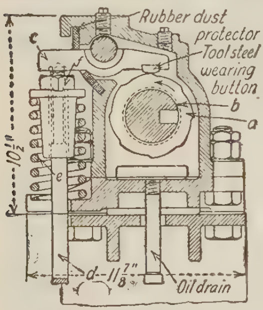

Fig. 27.—Vibrator for Leahy screen.

A 3 × 5-ft. screen at the Richard mill, Wharton, N. J., with 0.194-in. square aperture at 35° slope and 200 r.p.m. handled 28 tons of magnetite ore per hour, through ¾-in. round-hole plate, with 3 to 5 per cent moisture, at an efficiency of 92 per cent. With less than 1 per cent. moisture the efficiency rose to 98.5 per cent. At the Iron Mountain mill, Iron Mountain, Mo., a similar screen handled 19 tons per hr. of wet hematite ore with an efficiency of 99.6 per cent. and was underloaded. H. M. Roche (*PC*) believes that the screen could have handled 38 to 40 tons per hr. with 98 per cent. efficiency. These performances indicate a capacity of 9 to 12 tons per sq. ft. per 24 hr. per mm.

Lead-belt screen uses the principle of an unbalanced disk to cause vibration. The vibrator (Fig. 28) is mounted on two hickory rods (*19*) carried on the screen frame. Shaft (*5*), driven by pulley (*7*) carries, keyed to it, the heavy disk (*4*) which is unbalanced by coring out holes (*9*) and filling them with wooden plugs. The vibration caused by rapid rotation (1200 to 1250 r.p.m.) of the disk is transmitted through ball bearings (*6*) to the hammer (*1*) of which (*2*) is an integral part. A bronze bushing (*12*) and hardened-steel roller (*14*) are mounted on (*2*) and are surrounded loosely by the oblong ring (*15*) which is shrunk within the upper portion of transmitter (*16*), the lower end of which is attached to a cross-bar on the screen cloth. The roller (*14*) strikes the inside of ring (*15*) only at the top and bottom of its circular path, thereby transforming the circular motion of the hammer into up-and-down motion of the transmitter. The spring mechanism (*22*), (*23*), (*24*) and (*25*) is used on large screens to take some of the load off the transmitter.

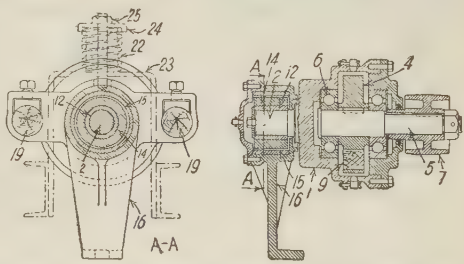

Fig. 28.—Vibrating mechanism of Lead-Belt screen.

At St. Joseph Lead Co. a 42 × 45-in. machine with 1.7-mm. wire cloth screens 25 tons per hr. wet, using spray water. The feed contains 45 per cent. −2-mm. material and the oversize 13.5 per cent. −2-mm. At the same plant a screen 33 in. wide × 7 ft. long with

9-mm. screen handles 33 tons per hr. of dry feed at 70 per cent. efficiency. At a St. Louis plant of the Laclede Gas Co. a screen with ⅜-in. cloth handles 25 tons of coke per hour.

Advantages of vibrating screens are high capacity, all of the screen surface is continually in use, there is less blinding than in other types, and greater ease of adjustment. The disadvantages are the danger of screen breakage if the cloth is too loose; flotation of fines at the surface of the bed by upward air currents in screens of large amplitude; loss of headroom in distributing feed and collecting products.

8. Traveling-belt screen

Callow traveling-belt screen (Fig. 29) is typical of this class. It consists essentially of an endless screen cloth (*a*) passing over rollers (*b*) so mounted that the upper surface is substantially horizontal. Rubber edgings are buttoned to the screen cloth to keep material on the screen. Feed is distributed over the width of the belt by means of a distributor, pulp is washed by sprays from box (*e*), undersize is carried away in chute (*f*) and oversize carried over the tail roller is washed off by spray from box (*g*) and discharged through chute (*h*). The standard size has two belts, each 2 ft. wide and 4 ft. center to center of rollers. The small size is single-belt, 2 ft. wide and about 2.5 ft. center to center of rollers. The usual speed is between 50 and 100 ft. per min., the lower speed for 8- to 20-mesh screening, the higher for 100- to 120-mesh.

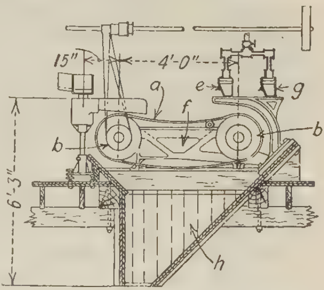

Fig. 29.—Callow traveling-belt screen.

Capacity, according to the manufacturer, is given by Table 41. *Truscott* rates the capacity at 4 tons per sq. ft. of total screen surface per 24 hr. per mm. aperture. This is substantially the average rate of the tests of Cox, Gibbons and Porter (*14 CMI 526*) as shown in Table 42.

Table 41. Capacity of Callow screen. (*Maker's catalog*)

Screen, mesh	Tons of feed per 24 hr. Standard duplex	Tons of feed per 24 hr. Small size, single-belt
20	250	62.5
30	200	50.0
40	150	37.5
60	125	31.2
100	75	18.7

Water required is 12 to 20 gal. per min. per duplex screen for 40- to 80-mesh screening. The maker's rating is somewhat lower at coarse sizes and higher at fine.

At Miami Copper Co. standard duplex screens equipped with 0.029-in. (0.74-mm.) rectangular-mesh cloth averaged 333 tons per screen per 24 hr. and for a month at a time handled as high as 435 tons per 24 hr. The pulp contained about 67 per cent. solids and no spray water was added. This is at the rate of 20.3 tons per 24 hr. per sq. ft. per mm. About 20 per cent. of the feed passed through the screen. Efficiency was about 60 per cent. The total cost in 1915 was $0.00598 per ton, made up as follows: operating labor, $0.00265; maintenance labor, $0.00078; screens, $0.00165; edgings, $0.00026; miscellaneous, $0.00064. At United Eastern Mining Co. two standard duplex screens, fitted with one 20-mesh and one 30-mesh belt on each screen, in closed circuit with Marcy mills took 120 tons per day each of original feed plus about 200 tons per day of circulating load or a total of 320 tons per day per screen, which is 22.3 tons per 24 hr. per sq. ft. per mm. The two screens were replaced by one Dorr simplex classifier and the capacity of the ball mills was increased to 260 tons. Comparative screen analyses are shown in Table 43. The efficiency of the

screen was 48 per cent. The finished product of the screen is somewhat smaller than that of the classifier, but against that fact is a set-off of $0.0175 per ton of original feed for screen and elevator operation, and 20 tons increase per day in ball-mill feed.

The tests of Cox, Gibbons and Porter (Table 42) seem to indicate that the efficiency of the screen is greater at 60- and 100-mesh than at 20-, 30- and 40-mesh; but the tests on the coarse screens were all run with relatively high percentages of solid and tests 7 to 10 inclusive indicate that dense pulps screen much less readily than thin pulps. It is probable that the difference in consistency explains the apparently discrepant drop in capacity per square foot per millimeter on the coarser screens. Tests 16 and 17 indicate that 65 ft. per min. is too low belt speed for 20-mesh screening.

Table 42. Performance of Callow screen. (*After Cox, Gibbons and Porter*)

−200	20.0	7.0	38.5	5.4	41.1

Breaking of screen cloth due to bending around the pulleys is the usual cause of failure, rather than wear.

9. Miscellaneous screens

A large number of screens of various descriptions has been advertised but few of them have found more than limited use in the mills. A few of the better known of these are as follows:

Pratt ore sizer. The screening surface is a six-sided pyramid with base up. Suspended within the pyramid is a vertical shaft carrying a box from which pulp is discharged through pipes and distributed over the screening surfaces. A diaphragm placed centrally collects oversize from the upper part of the screening surface and feeds it back into a box on the shaft from which it is again distributed over the lower part of the screen. Undersize is collected in a housing and spouted away from the machine, while oversize falls through another spout.

Drum screen consists of eight plane screening surfaces forming the sides of an octagonal prism carried by spiders mounted on a horizontal shaft which revolves slowly. Material is fed through a distributing chute onto the top screen, undersize passes through the screen and is collected in a trough and oversize is washed off into a hopper.

King screen, which has been used to some extent in Broken Hill mills (*27 MM 331*) is of the drum type with screen cloth supported between peripheral rods, thus forming the screening surface into outwardly concave cylindrical arcs or troughs. The usual number of troughs is 12 for a screen 3 ft. diameter by 3 ft. long. A screen covered with 30-mesh cloth, making 8 r.p.m., taking about 150 tons of feed per 24 hr. had an efficiency of 59 per cent.

Gyratory screens have been manufactured both for coarse and fine screening. Coxe screen consists of several superimposed sieves slanted toward one corner, all carried in a common gyrating frame driven at 130 to 180 r.p.m. It has found some use in coal sizing but the mechanism is relatively complicated and expensive and maintenance cost is high.

Screenless sizing may be effected by taking advantage of the fact that when a mass of particles of mixed sizes is shaken so as to loosen the mass, the smaller sizes work to the bottom. McKesson-Rice sizer (Fig. 30) is built on this principle. It consists of a series of corrugated decks carried on a framework that is shaken parallel to the corrugations by an eccentric mechanism, the decks being sloped at 30 to 40° from the horizontal in a direction at right angles to the corrugations. The standard size of deck is about 6 × 8-ft. Corrugations are of different sizes on the different steps or decks, the coarsest corrugations being used on the first deck. Rate of shaking is 250 to 300 strokes per min.; amplitude, ¼ to ¾ in. Under the influence of the shaking motion the particles stratify with the coarsest on top and these surface particles roll down the slope to the edge of the machine and are caught in the proper compartment. The finer material is carried forward by the shake and dropped onto the next deck having finer corrugations, when again the coarser material comes to the top and rolls down over the balance and is caught in its proper compartment. This process is repeated as many times as desired and a corresponding number of grades are obtained. Screenless sizers have not been employed in ore-treatment plants.

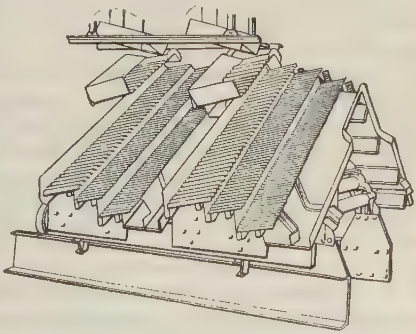

Fig. 30.—McKesson-Rice screenless sizer.

SECTION 6

CLASSIFICATION

1. Introduction

Classification is an operation in which a mass of grains of mixed sizes and different specific gravities is allowed to settle in a fluid which may be either in motion or substantially at rest. SORTING is another name for the same operation. The fluid ordinarily employed is water, but sometimes air is used. The velocity and direction of the fluid currents are closely controlled. The following general statements apply to the movements of the solid particles.

1. The relative falling velocities of particles of the same specific gravity and the same shape are dependent upon the sizes of the particles, the larger (and heavier) falling the more rapidly.

2. If particles are of the same size and shape but of different specific gravities, the most dense (heaviest) particles settle most rapidly.

3. If particles are of the same weight in a given fluid, but of different shapes, their falling velocities will probably differ; particles most nearly spherical will fall most rapidly, those most tabular most slowly.

4. Resistance to fall in a given fluid medium is dependent upon the velocity of the falling particle. Resistance varies as the ½-power of the velocity when the latter is very small, as the square when the velocity is large, and as some intermediate power or powers in the transition range.

5. Velocity of fall in a given fluid medium, all other things being equal, varies as the squares of the diameters of the particles when these are very small, as the ½-power of the diameters when the particles are relatively large, and as an intermediate power or powers in the transition range.

6. Resistance to fall increases with the density of the medium.

7. Resistance to fall increases with the viscosity of the medium. This increase is relatively greater the smaller the particle.

Formulas for falling bodies. When a body falls in a vacuum under the influence of gravity alone, its velocity v at any distance h from the starting point is given by the equation $v = \sqrt{2gh}$, g being the acceleration due to gravity. Inspection of the equation shows that the velocity at any point is dependent upon the distance from the starting point only. If the body falls in a fluid medium, its velocity at any given distance from the starting point is always less than had the fall been in a vacuum, due to the resistance offered by the medium. The nature of this resistance differs according to the velocity of the body. When velocity is low, no considerable disturbance is set up in the body of the fluid by the passage of the particle; the film or layer of fluid

in contact with the particle moves with it while the body of the fluid a short distance away is at rest. Substantially all of the resistance to movement is due to the viscosity of the fluid. Such resistance may be called VISCOUS RESISTANCE. When the velocity of the body is high the principal resistance to its motion is that offered by the fluid to bodily displacement from the path of the particle. The kinetic energy imparted to the fluid displaced is dissipated in eddying and turbulence. The effect of the viscosity of the medium is relatively small. This resistance is variously called EDDYING RESISTANCE and TURBULENT RESISTANCE. In all cases acceleration decreases rapidly and the body quickly attains a uniform terminal velocity.

Law of viscous resistance. Stokes, in 1850 (*Camb. Phil. Trans.*, IX) deduced theoretically a formula for the terminal velocity of a small solid sphere falling freely under the influence of gravity in a viscous fluid. At the beginning of such fall the pull of gravity on the sphere exceeds the resistance of the fluid and the particle is accelerated. With increasing velocity the frictional or viscous resistance of the fluid increases until a point is reached where the resistance is just equal to the gravity pull. Thereafter the body falls at uniform velocity. According to Stokes, at this stage resistance equals $6\pi\mu aV$, where μ = viscosity of the fluid, a = radius of the sphere, and V = the constant terminal velocity. The gravitational pull on the sphere is $\frac{4}{3}\pi a^3 g(\sigma - \rho)$ where g = acceleration constant, σ = specific gravity of the sphere and ρ = specific gravity of the fluid. Then $6\pi\mu aV = \frac{4}{3}\pi a^3 g(\sigma - \rho)$, and

$$V = \frac{2}{9}a^2 g\frac{(\sigma - \rho)}{\mu}. \qquad (1)$$

Allen (*50 Phil. Mag. 323, 519*) has confirmed Stokes' formula experimentally for the rise of air bubbles in water and in aniline and for the fall of solid spheres in the same liquids. When water is the medium, μ and ρ may be taken as constants and equation (1) becomes

$$V = KD^2(\sigma - 1), \qquad (2)$$

where K is a constant whose magnitude depends on the units employed.

Law of turbulent resistance. Newton (*Mathematical Principles of Natural Philosophy, Book II*) states that when a body falls in a non-viscous medium the resistance to fall is proportional to the square of the velocity of the body. Allen (*loc. cit.*) has proved experimentally that for the fall of steel spheres in water the resistance R after constant velocity has been attained is given by the equation

$$R = K\rho a^2 V^2, \qquad (3)$$

and that the value of the constant K for these particular conditions is 5.50×10^{-4}, when c.g.s. units are employed. By equating this value of the resistance to the gravitational pull on the falling body a formula for V may be derived. Thus

$$K\rho a^2 V^2 = \frac{4}{3}\pi a^3 g(\sigma - \rho),$$

and

$$V = \sqrt{\frac{4\pi a g(\sigma - \rho)}{3K\rho}} = C\sqrt{D\frac{(\sigma - \rho)}{\rho}}, \qquad (4)$$

where D = diameter of sphere and $C = \sqrt{\frac{2\pi g}{3K}}$.

Allen's equation for velocity of fall of spheres in the size range coarser than that covered by Stokes' law (Law of viscous resistance) and finer than that covered by Newton's law (Law of turbulent resistance) is

$$V = K\left(\frac{(\sigma - \rho)g}{\rho}\right)^{2/3}\frac{a - ha'}{\nu^{1/3}}, \quad (5)$$

where K and h are constants, a' is the critical radius marking the maximum size of sphere obeying Stokes' law, and ν is the kinematic coefficient of friction $= \mu/\rho$. Allen's experiments show that K = nearly 0.5, h = nearly 0.4 and $a' = 0.0085$ cm. Allen found this formula applicable to air bubbles varying from 0.13 to 1.10 mm. diameter when rising in water and in aniline; to paraffin spheres between 0.69 and 3.16 mm. diameter rising in aniline and to amber spheres from 1.14 to 3.46 mm. diameter falling in water. For none of the materials do the experimental data indicate that the upper size limit of particles obeying the linear equation is reached. The experiments with steel balls do, however, indicate that at velocities of about 750 mm. per second a change in the resistance to fall occurs and Allen infers that this may mark the point of change from the linear equation to the equation involving turbulent resistance alone. The data tell nothing as to the lower-size limit with paraffin and amber. With air bubbles smaller than 0.13 mm. marked divergence from the linear equation occurs, but this may be due to solution of the air.

Free fall of mineral fragments in water has been carefully investigated by Richards (*38 A 210*). His results on rates of settlement of quartz and galena are summarized in Fig. 1. The figures plotted are the averages of the falling rates of 100 grains for each size. Maxima and minima vary 15 to 50 per cent. from these averages. The curves show that for sizes larger than about 1.6-mm. the free-falling velocities of the particles in water vary as $D^{1/2}$. (See lines (a) and (d), Fig. 1.) By writing equations for lines (a) and (d) and equating the value of V to the value of V from equation (4), the values of C in the latter equations may be found and these equations equations become

$$V = 92\sqrt{D(\sigma - 1)} \text{ for quartz}, \quad (6)$$

and

$$V = 104\sqrt{D(\sigma - 1)} \text{ for galena}, \quad (7)$$

when D is in mm. and V in mm. per sec. For quartz between 0.16- and 0.015-mm. diameter and galena between 0.12- and 0.007-mm. diameter the free-falling velocities vary as D^2 (see lines (c) and (f), Fig. 1) and the equations of fall can be written

$$V = 450D^2(\sigma - 1) \text{ for quartz}, \quad (8)$$

and

$$V = 640D^2(\sigma - 1) \text{ for galena}, \quad (9)$$

with units the same as in the preceding equations. In the intermediate size ranges for the two minerals Allen's linear equation does not hold. The behavior of quartz particles is closely represented by the equation

$$V = 95D^{0.83}, \quad (10)$$

and galena

$$V = 263D^{0.60}. \quad (11)$$

The specific gravity of the solid is, of course, a factor in the falling velocity in this size range, as in the other ranges, but disappears into the constant and the exponent of D, due to the empirical method of developing the equation.

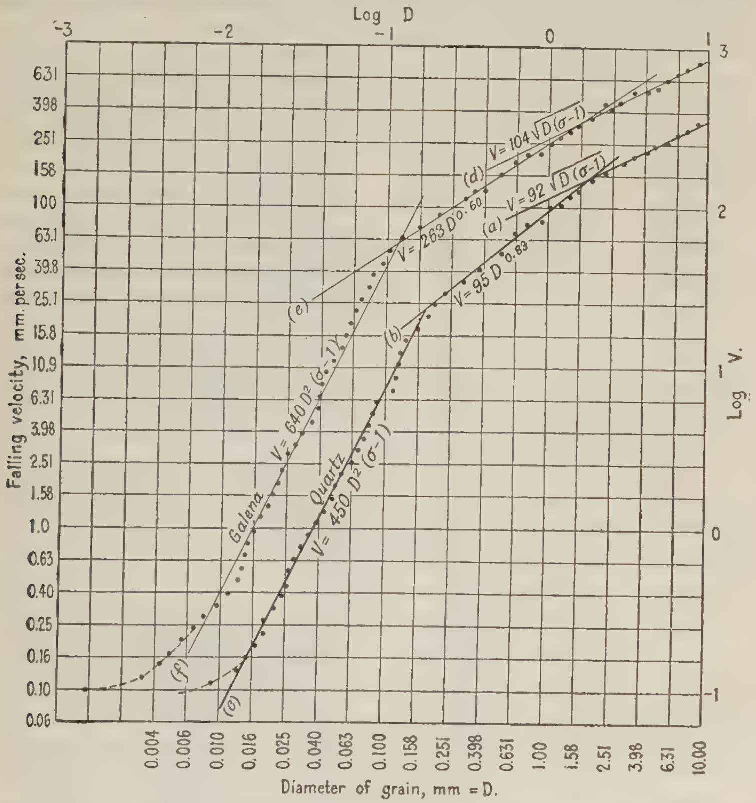

FIG. 1.—Free fall of mineral fragments in water.

Table 1 gives falling velocities in water, calculated from the appropriate formulas, for quartz particles of sizes corresponding to Tyler testing sieves.

For other minerals than quartz and galena the approximate falling velocities of particles can be obtained by use of the multipliers given in Table 2, which is calculated from experimental data given by Richards (*41 A 396*). To determine, *e.g.*, the falling velocity of a 1-mm. grain of cassiterite, divide by 0.34 to get the diameter of a quartz grain of corresponding settling velocity. Substitute the quotient for D in the equation heading the column and solve for V, which will be the figure desired. If the equivalent diameter of quartz is not within the range to which the equation heading the first-tried multiplier column is applicable, use the multiplier in the other column. The answer will be an approximation only, but well within experimental limits.

Free-settling ratio. If a mixture of mineral grains of different sizes and different specific gravities is subjected to a series of rising water currents of

diminishing velocities, the coarser grains will sink in the currents of higher velocity and the smaller in the slower currents. There will be a final overflow of the finest material. In each of the products except the first and the last there will be a distinct grouping of the minerals according to size, the coarser grains being the lighter mineral and the finer the heavy mineral. The ratio of the average size of light mineral in any of these products to the average size of the heavy mineral in the same product is the free-settling ratio. Table 3 (*41 A 396*) gives free-settling ratios of quartz and galena as determined experimentally by Richards and the theoretical average ratios determined from equations (6) and (7), (8) and (9), and (10) and (11). Estimates of probable free-settling ratios of any two minerals at any given velocity can be determined by use of Table 2.

a Reckoned as the arithmetical mean between the retaining screen and the screen preceding.

Example. To determine the probable free-settling ratio of quartz and chalcocite in a product that falls in a rising current of 100 mm. per sec. velocity and rises in a current of 150 mm. per sec. The largest quartz particle to settle will be, theoretically, 1.66-mm. diameter (from equation 6); the smallest, 0.94-mm. (from equation 10). The average diameter of quartz may be taken as the arithmetical mean of these extremes, or 1.30-mm. The largest chalcocite particle will be $0.44 \times 1.66 = 0.73$-mm. diameter and the smallest, $0.61 \times 0.94 = 0.57$-mm. The mean chalcocite diameter is 0.65-mm. and the free-settling ratio $1.30/0.65 = 2$.

Hindered-settling. If any constriction is placed in the tube in which a current of fluid is rising and solid particles are falling, the velocity of the fluid across the constricted portion is greater than that above and as a result certain of the solid particles fall to the constriction but cannot fall further. They remain, therefore, in a mass in the tube, above the constriction. If the particles are not too large and the ratio of area of constricted portion to tube cross-section not too small, the mass of particles above the constriction will teeter, as the solids in a quicksand. Under such circumstances particles settling are hindered by collision with particles in teeter and the mixture of solid and fluid acts as though it were a fluid of greater density than the fluid employed. The settling rate of solid particles in the tube is,

consequently, decreased. The decrease for any given particle is proportionately greater, the less the specific gravity, because, all other things being equal, V is proportional to $(\sigma - \rho)/\rho$.

Table 2. Multipliers for use in determining free-settling velocities of mineral grains. (*After Richards*)

Mineral	Sp. gr.	Multipliers for quartz diameters in equation

Copper	8.48	0.43	0.29

Table 4 gives hindered-settling velocities for several minerals as determined by Richards (*41 A 396*). In this table, under the caption "Hindered-settling" are given figures determined by dividing the volume of water, in cu. mm. per sec., passing through the sorting tube by the area of the tube in sq. mm. at the time when the solids were in FULL TEETER, *i.e.*, all grains in motion under the action of the rising current but none actually being carried upward away from the mass. The velocity figure is not, of course, the actual interstitial velocity of the water.

Table 3. Free-settling ratios of quartz and galena. (*After Richards*)

Such substitution in equation 4, *e.g.*, of values of V and D for galena from the first five horizontal lines of Table 4, gives a value of 4.8 for ρ, which would allow for but 41.5 per cent. voids. Corresponding figures for quartz are $\rho = 2.23$ and percentage of voids $= 25$. Since the densest packing of equal-sized spheres leaves 26 per cent. voids, these figures would require that sized mineral fragments of irregular shape in full teeter should be equally closely packed. This is not reasonable.

Table 5. Free- and hindered-settling ratios of various minerals with respect to quartz (*After Richards*)

	Free-settling ratios for 228.6 mm. per sec., fastest grains	Hindered-settling ratios

a Anthracite to quartz.

Hindered-settling ratios are consistently larger than free-settling. Table 5 (*41 A 396*) compares the free- and hindered-settling ratios of various minerals with respect to quartz. In the same paper Richards records a test in which quartz-galena hindered-settling ratios as high as 8.0 were obtained in a small, carefully-run experimental classifier.

Types of classifiers

Classification is used in mills for several different purposes. The type employed depends upon the character of service. Hydraulic classifiers are used to divide a ground pulp into a number of GRADES or SORTS for subsequent treatment on gravity concentrating machines. These classifiers are so named because of the fact that fresh water, often called HYDRAULIC WATER,

is added to them in order to supply the rising current of water against which settlement of solid particles is effected. There are two general types, known respectively as free-settling and hindered-settling, and many varieties of each class. Sand-slime separators are used to determine the maximum size of particle discharged from a fine-grinding circuit, or to separate a ground product into sand and slime for different kinds of subsequent concentrating or metallurgical treatment. There are two principal types, known respectively as mechanical classifiers and cone classifiers. The first type is commonly preferred in the U. S.; the second was developed and has had wide use in South Africa. An automatic-discharge cone has recently met with considerable favor in this country.

2. Free-settling hydraulic classifiers

General. Classifiers of this type are characterized by the fact that the sorting column is of the same cross-sectional area throughout its length. A large number of types has been built and used. These may be grouped into two classes, *viz.:* launder type and tank type. LAUNDER CLASSIFIER is essentially a launder with sorting columns attached to the bottom at convenient intervals. If the upper end of the sorting column comes directly to the bottom of the launder, the machine is called by *Richards* a SHALLOW-POCKET CLASSIFIER; if the launder is deepened above the sorting pocket, *Richards* calls the machine a DEEP-POCKET CLASSIFIER. TANK CLASSIFIER consists of a relatively deep V-shaped trough or tank with the sorting columns attached to the bottom thereof.

Shallow-pocket free-settling classifiers include many of the early forms of hydraulic machine, such as the Lake Superior hog-trough, Calumet, Tamarack, Yeatman, Ferraris, Evans, etc. (*1 OD 390 et seq.*)

Evans classifier (Fig. 2) is typical. It consists of a launder (A) with inclined bottom to which are attached a plurality of pressure boxes (D) opening by means of adjustable rectangular transverse openings (B), (C), into the bottom of the launder. Water is introduced into the boxes (D) through pipes (F), a part flows out through spigot openings (G) and the balance rises through the openings (B, C) into the launder. Water input is regulated to give maximum rising velocity at the first box and minimum at the last. Feed enters as marked, with sufficient water (about 75 per cent. by weight) for ready transport, and flows along to the first sorting column where its horizontal rush is lessened by baffle (E). Some segregation of coarse and heavy solid to the bottom of the horizontal stream occurs in the flow along the launder. The largest and heaviest particles drop through the slots (B, C) and pass out through the spigot opening (G) while the solid unable to settle passes on to the second column. The coarsest and heaviest of the remaining particles are here taken out and the process continues until the lightest solids, unable to settle in the relatively slow current of the last sorting column, leave the classifier. Performance is shown in Table 6.

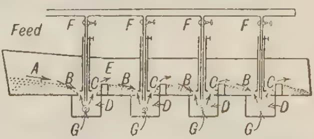

FIG. 2.—Evans classifier.

Calumet classifier (Fig. 3) is used at BUNKER HILL AND SULLIVAN MINING Co. to prepare the sand discharge of an Esperanza drag classifier for table treatment. It consists of an inclined trough (a) with a series of settling

pockets (*b*), through one side of which hydraulic water is led by pipes (*c*) while the spigot product discharges through the other side. A baffle (*d*) above the spigot discharge prevents short circuiting of material to the spigot.

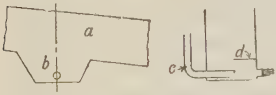

FIG. 3.—Calumet classifier.

The machine at the BUNKER HILL AND SULLIVAN mill treats 50 tons solid per day; water consumption, 600 gal. per ton. Screen tests of products are given in Table 7.

Settling ratios obtained in shallow-pocket free-settling classifiers are far below the theoretical. Much slime appears in the earlier spigot products

because of the presentation of slime directly to the sorting column and much oversize goes to later spigots because the shallow pockets fail to hold it long enough to insure an opportunity to settle.

A free-settling launder-type classifier that can be made up readily around any plant is shown in Fig. 4 (*111 J 911*). Both the 6-in. and 3-in. pipes are welded to the cover plate and the hydraulic-water pipe is welded to the 6-in. pipe.

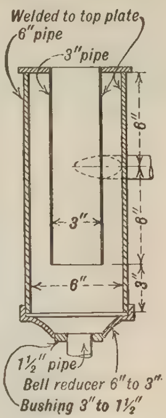

Fig. 4.—Simple free-settling launder-type classifier column.

Deep-pocket free-settling classifier is typified by the Richards vortex classifier (Fig. 5). It differs from the shallow-pocket apparatus by providing pockets above the sorting columns of sufficient size and depth to effect a rough segregation of the feed to the column, sending along immediately most of the material that could not settle in the sorting column proper and holding back material that might settle in the column long enough to give it an opportunity to do so. The vortex fitting used at the bottom of the sorting columns in this classifier is shown in Fig. 6. Water entering the tangential inlet pipe takes on a swirling motion around a vertical axis and retains this motion in rising through the sorting column, with the result that eddies around horizontal or inclined axes are eliminated. This elimination goes to prevent the presence of fine sand and slime in the spigot products. The ideal condition in the sorting column is a uniform current vertically upward,

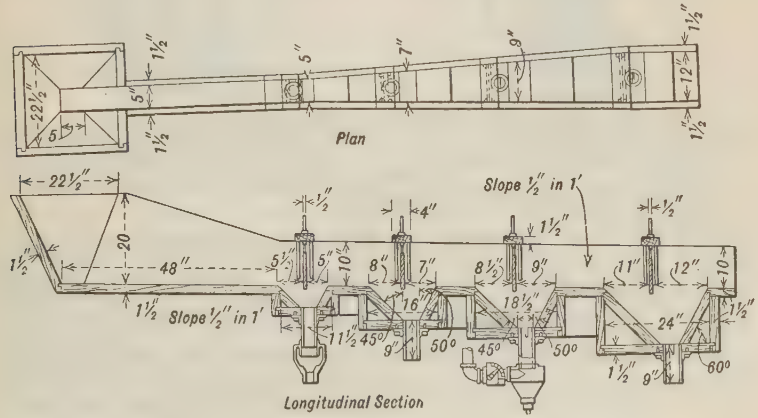

Fig. 5.—Richards launder-type vortex classifier.

but this cannot be attained. A home-made substitute for the vortex fitting is shown in Fig. 4. It is intended to bolt to the bottom of a roughing pocket. Performance of a 3-spigot vortex classifier is shown in Table 8.

Free-settling tank classifier is shown diagrammatically in Fig. 7. Sorting columns are of the same types as used on launder classifiers but the tank affords better opportunity for keeping slime away from the sorting columns. The use of free-settling hydraulic classifiers is past in well-designed mills

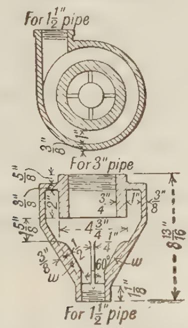

Fig. 6.—Richards vortex fitting.

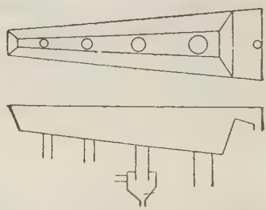

Fig. 7.—Sketch of free-settling tank classifier.

owing to their inefficiency and the superior results attained by hindered-settling machines. Mill operation of a free-settling classifier never yields settling ratios that approach the theoretical.

Fig. 8.—Methods of obtaining constriction in hindered-settling sorting columns.

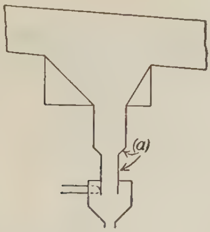
3. Hindered-settling hydraulic classifiers

General. Hindered-settling classifiers differ from free-settling in one characteristic only, *viz.:* that the sorting column is constricted at the lower end. This constriction may be obtained in any way. Several forms of hindered-settling sorting columns are shown in Fig. 8. The effect of the constriction has been considered in Art. 1. The same general types are found in hindered-settling as in free-settling mill machines, viz.: launder and tank.

Launder-type hindered-settling hydraulic classifiers

The simplest of these is a machine obtained by placing a reducer and a short pipe nipple of smaller size on the lower end of the sorting column of a Richards vortex classifier (Fig. 5), and placing the vortex fitting on the lower

end of the added nipple. Fig. 9 is a sketch of one spigot of such a classifier. Such a change in an existing classifier will result in a reduction in capacity, but by replacing the sorting column of the existing classifier by a teeter column of larger diameter, dropping the existing column to a position below the added member, capacity will be maintained. For discussion of the ratio of diameters of sorting column and teeter column, see Art. 4.



a. Reducer and nipple added to change classifier from free-settling to hindered-settling.

Fig. 9.—Sketch of one spigot of Richards hindered-settling vortex classifier, launder type.

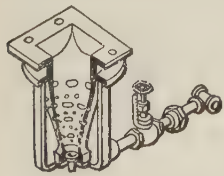


Fig. 11.—Richards hindered-settling sorting column.

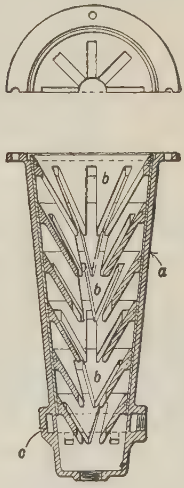

Fig. 10.—Deister cone-baffle classifier.

Deister cone-baffle classifier column (Fig. 10) consists of a downwardly-converging cylindrical casting (*a*) in which are suspended a number of slotted cone-shaped castings (*b*) with slots staggered vertically as shown. Water enters radially through a plurality of small holes from the pressure chamber (*c*). The column may be bolted directly to the bottom of a launder, but is better placed on the lower side of a roughing pocket.

This device had its greatest use in the gravity-concentration flow-sheet at Miami, prior to the adoption of flotation. A 12-spigot launder treated −10-mesh (1.651-mm.) drag-classifier sand. Table 9 gives sizing tests of the spigot product of a single-column machine under different operating conditions.

Richards hindered-settling launder-classifier column is shown in Fig. 11. The converging conical sorting chamber is perforated with vertically-alternating rows of radial and tangential water inlets which serve to maintain free movement and maximum fluidity in the mass of teetering grains.

Fig. 12 shows graphically the performance of a 10-spigot machine at Miami Copper Co.

At Clausthal (*100 J 426*) the 4-spigot launder-type hindered-settling classifier shown in Fig. 13 is used to treat −1.4-mm. undersize of trommels. Overflow is sent to a V-box, which is run without hydraulic water to prepare shaking-table feed.

chamber (*c*) are prevented by the rotating valve (*d*) on the water inlet. This valve is opened and shut 200 to 400 times per min. by pulley (*e*), belt-driven, the higher speeds being used for the finest pulps. Water hammer is eliminated by the air chamber above the valve and the air compressed herein

when the valve is closed gives additional velocity to the water in the column as the valve opens. The assembled unit, carried by the trapezoidal roughing pocket (*a*), is bolted to the bottom of a launder. The machine is made in five sizes, based on the inner diameter of tube (*c*), *viz.*: 2½-, 3-, 4-, 5- and 6-in. Fall from the top of the roughing pocket to the lowest point of the spigot is 28 in. in the 2½-in. machine and 38 in. in the 6-in. machine. Capacity and water consumption may be estimated roughly from Figs. 15 and 16 re

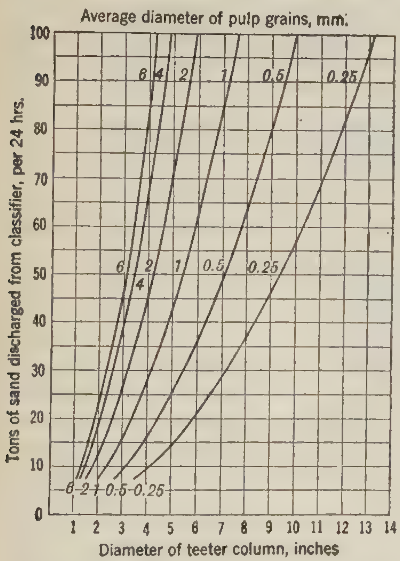

Fig. 15.—Capacity of Richards launder-type pulsator classifier (*after Denver Eng. Wks.*)

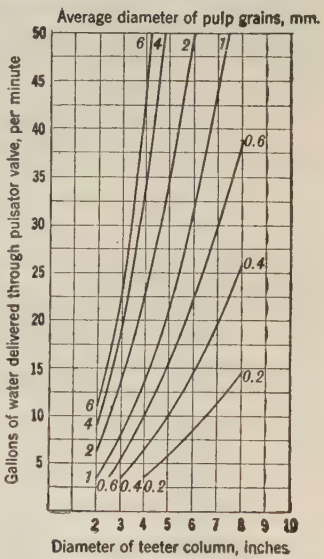

Fig. 16.—Water consumption of Richards launder-type pulsator classifier (*after Denver Eng. Wks.*)

spectively. Design should follow Art. 4. Performance of a 5-spigot machine is shown in Table 10.

TANK-TYPE HINDERED-SETTLING HYDRAULIC CLASSIFIERS

These classifiers have been more generally used in recent gravity-concentration installations than the launder types. The best-known are the Richards, Richards-Janney, Richards inverted-pulsator, and Anaconda.

Richards hindered-settling tank classifier consists of the usual flaring V-tank, with inclined bottom, to which are attached a number of Richards hindered-settling sorting columns (Fig. 11).

Performance. At Moctezuma Copper Co. a 6-spigot machine treating Chilean mill discharge through 0.08-in. screen at the rate of 400 to 450 tons solid per 24 hr. in a pulp containing 75 per cent. moisture made spigot products as shown in Table 11. Moisture in the feed was about 75 per cent. At Liberty Bell a 3-spigot machine with 2-in., 2½-in. and 5-in. columns treating 40 tons per 24 hr. made the products shown in Table 12. Water consumption was about 1000 gal. per ton of feed.

Richards-Janney classifier (Fig. 17) is of the tank type with hindered-settling sorting columns and various important features that give large capacity, steady operation, low water consumption and considerable flexibility. It consists of a number of pyramidal settling tanks, increasing in size from feed to discharge end, so joined that the tops of the dividing partitions formed by the junction of adjacent walls are well below the overflow level. To the bottom of each pyramidal frustum is attached the classifying mechanism proper, consisting of a cylindrical teeter chamber (*a*), converging at the bottom to the cylindrical glass-walled sorting column (*b*) below which is a tangential hydraulic-water inlet (*c*). These constitute the elements. The additional features are the rotating stirring arms (*d*) carried on a hollow spindle (*e*) depending from the worm gear (*f*) which is driven by a worm from shaft (*g*). Cams (*h*) on the upper side of gear (*f*) operate a lifting arm on the tappet rod (*i*) which carries on its lower end a rubber ball-valve that seats on a bushing (*j*). The valve is thereby periodically opened and discharges into the retarding chamber (*k*) which in turn discharges through a pipe-and-plug spigot (*l*). The rate of discharge is controlled by the size of the spigot opening and by the air cock (*n*). Water inlet to each column is regulated by a dial valve (*m*). The stirring arms make about 1.5 r.p.m. They prevent the formation of sand banks in the teeter column and also tend to prevent the formation of eddies with downward components of motion. The glass sorting column, by permitting observation of the actual sorting operation, makes regulation of the classifier easier than otherwise. The intermittent discharge effected by the ball valve makes it possible to discharge a thick spigot product through a large opening and thus decrease water consumption while eliminating clogged spigots. The retarding chamber prevents serious downward rushes of pulp, which would entirely disarrange classification, when the ball-valve opens.

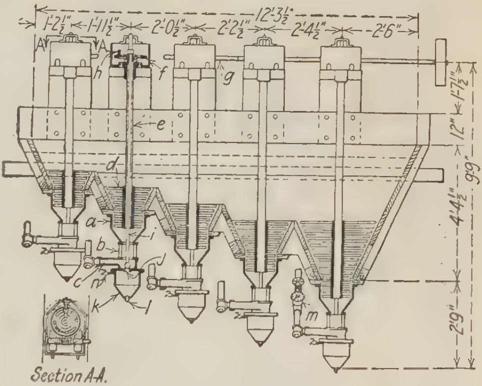

FIG. 17.—Richards-Janney classifier.

Performance is shown in Table 13. Both of the CHINO machines are apparently overloaded, with the result that there is much slime in the spigot products and much fine sand overflowing. The machine on zinc ore is doing the best work from the point of view of size differentiation in products. The moisture content of the products is reasonably consistent and characteristic and, compared with the spigot discharges from other classifiers, shows the advantage of intermittent retarded discharge.

Richards inverted pulsator classifier (Fig. 18) consists of a tank (*a*) with screen bottom, divided by partitions extending nearly to the screen into seven compartments of unequal area, six of the compartments being fitted with overflow spouts (*b*). The tank is set on top of a compartmented water-distributing tank or hutch (*c*), fed by a manifold from a pulsating cock. Each of the overflow compartments in the upper tank constitutes a settling

column with a constriction at the bottom furnished by the screen. The velocity of the water rising in the individual compartments depends upon their cross-sectional area and upon the height of the overflow lip. Pulp introduced into the feed compartment passes to the bottom of the first compartment where the finest material is lifted out. The balance is moved along the screen to the next compartment under the horizontal impulse of new feed arriving. Each compartment removes its quota until the last is reached and here an extra-strong current induced by lowering the spout an inch or more below the others raises all but the coarsest heavy mineral. This may be discharged intermittently or continuously through spigot (*d*). Hutch spigots are provided to draw off any fine material that passes through the screen. Usual tank widths are 3- and 4-in.

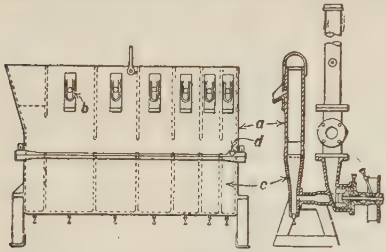

Fig. 18.—Richards inverted pulsator classifier.

Performance at Anaconda is shown in Table 14. Speed and water consumption in this test are higher than usual and tonnage is low. A 4-in. machine can probably treat 125 to 175 tons per 24 hr. of −2-mm. copper ore or 150 to 200 tons of lead ore at the same size. With finer feeds the capacity will be less.

This classifier can be made to do as nearly perfect work as any classifier that has ever been devised, but it is extremely sensitive to feed changes, requires rather close attention, and consumes a large amount of water, ranging from 1000 to 1500 gal. per ton of ore treated. Any dirt in the feed water, such as wood or plant fragments, lodges on the under side of the screen and by blinding it cuts down current velocities. The upper tank (*a*) must then be lifted off and the screen cleaned. A run of coarse material may cause building up at the bottom of the last compartment so that this compartment is cut off and the entire classification disarranged.

Richards pulsator classifier, tank type (Fig. 19) is used by the New Jersey Zinc Co. at the Franklin and Ogdensburg mills. Pulsating water rises through grids (*a*) in the bottom of the usual flaring V-tank and spigot products are drawn from the bottom of the hopper-shaped pressure boxes (*b*).

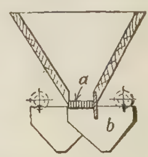

Fig. 19.—Richards pulsator classifier, tank-type, at New Jersey Zinc Co.

At Franklin each machine treats about 100 tons per 24 hr. and consumes about 450 gal. of water per ton of solids. Valves are run at 120 rev. (240 pulsations) per min. and each machine consumes 3 hp. Spigot openings vary from ½-in. diameter at the feed end to ⅛-in. at the overflow end. Choking causes about 5 per cent. lost time. Screen tests of feed and products are given in Table 15. At Ogdensburg the total load is 120 tons per 24 hr.; water consumption, 400 gal. per ton of feed and valve speed 130 r.p.m. Sizing tests of feed and products are given in Table 15.

Fahrenwald classifier (sizer) (Fig. 20) is of the hindered-settling tank type, but the spigot product is drawn from the bottom of the teeter chamber without passing through the constriction or being elevated to an overflow and the rate of discharge is automatically controlled by the pulp density in individual teeter chambers. (*A*) is a tank in which the bulk of the slime is roughed out. Below (*A*) is the trapezoidal tank (*B*), with vertical side walls, divided into compartments (*b*) by means of the partitions (*b′*). The perfor-

ated constriction plate (*c*) separates the teeter chamber from the individual hydraulic-pressure chamber (*d*) below. Hydraulic water is supplied to the pressure chambers through individual pipes from a header. Observation of the individual teeter columns is afforded by means of glass windows. Spigot discharge is effected as follows: As classified sands accumulate in the teeter chamber the pressure rises in (*d*) and water is forced up through pipe (4), which connects with (*d*), into chamber (5) and pipe (10) until it stands at some level above (9). The pressure in chamber (5) due to this standing column of water raises the soft-rubber diaphragm (9) and with it pipe (10) and rod (11), which

latter is pinned through hole (12) in such a way that rise of (10) engages the pin. Rod (11) carries ball valve (2) at its lower end and this ball, when lifted, permits classified sand to pass from above the constriction plate through pipe (14) out of the classifier. Drain plugs are provided at the bottoms of chambers (*d*) to discharge any sands that pass the constriction plate. The height of chamber (5) must be adjusted to correspond with the density of the pulp in the individual teeter chamber. This is done by loosening the set-screw (15), which clamps stem (7). For feeds passing 14-mesh the heights of the chambers above pulp level in (*A*) range from 10 to 16 in. in the first compartment to 3 to 5 in. in the last.

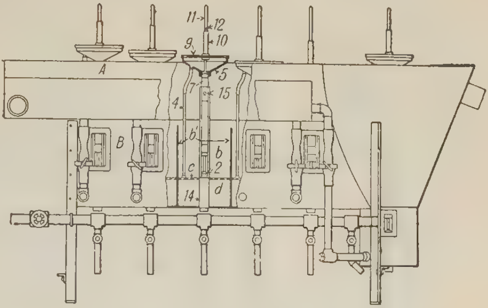

Fig. 20.—Fahrenwald classifier.

Performance. The inventor states (*U. S. Bur. of Mines, Reports of Investigations, Ser. No. 2618, June, 1924*) that a 10-spigot machine at Bunker Hill and Sullivan, West mill, treated 225 tons per 24 hr. with a water consumption of 320 to 480 gal. per ton. Sizing-assay test of the feed and products is shown in Table 16.

Anaconda classifier (Fig. 21) consists of a conical roughing chamber (*a*) atop a hindered-settling column (*b*) formed by placing a perforated plate (*c*)

in the path of the rising water. At Anaconda the lower casting (*d*) and the length of the cylindrical part of the upper casting were made the same for all sizes of classifier but the shape of the cone was varied according to the table of dimensions given in the figure. Small, steep cones were used for coarse separation, larger and more obtuse cones for de-sliming.

Performance at Anaconda under various feed conditions is given by Ammon (*46 A 277*) and summarized in Table 17. The volume of feed pulp is the important factor in de-sliming

classifiers. Experiment at ANACONDA showed that this should not exceed 250,000 gal. per 24 hr. with a 7-ft. cone, if it was desired that the overflow should all pass 200-mesh. From 200 to 250 tons solid could be handled in this volume of pulp. The rising velocity necessary in the sorting column is dependent upon the size of the sands; it must be sufficient to maintain teeter. Table 17 shows the results of 3 out of 11 tests on a 28-in. machine fitted with a feed cone. The tests show that the performance of the machine is not greatly affected by large changes in feed tonnage. Had the amount of hydraulic water not been reduced in test No. 2 coincident with the increase in +1.41-mm. material, it is probable that the rise in proportion of spigot product and fall in proportion of total free mineral therein would not have occurred. The work of 40-in. classifiers at the AMERICAN ZINC, LEAD AND SMELTING Co. mill when working in closed circuit with tube mills, compared favorably with that of a Dorr classifier in the same service, the amount of water in the overflow was not excessive and the tube-mill feed could be thickened by the addition of drier material with the spigot product.* See Table 18.

Delano classifier (Fig. 22) is used in de-sliming service. Constriction of the sorting column is effected by the conical wooden plug at the apex of the cone. Capacity of a machine 5 ft. 6 in. diameter treating Missouri lead ores is 350 to 400 tons solid per 24 hr.; water consumption 120 gal. per min. (*57 A 430*). Spigot opening, 0.75 to 1 in.; moisture in spigot product, 50 per cent. Sizing tests of feed and products when thus working are given in Table 19.

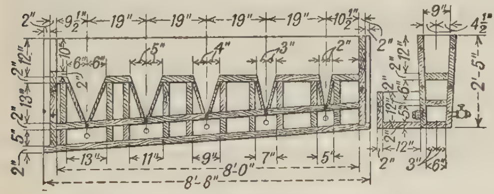

Fig. 23.—Dalton classifier.

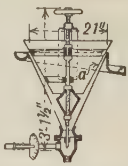

Fig. 24.—Double-cone classifier.

Double-cone classifier (Fig. 24) utilizes an adjustable inner cone (a) to increase and equalize the velocity of the rising current above the sorting column and thus enable overflow of sand without undue water consumption.

At the Midvale plant of the U. S. Smelting, Refining and Mining Co., a 20-in. machine handles 275 tons per 24 hr. of −1.3-mm. feed, discharging sand through a ¾-in. spigot with 70 per cent. moisture; a 30-in. machine treats 240 tons of −0.9-mm. feed; spigot, 1⅟₁₆-in.; moisture in sand discharge, 75 per cent.; a 40-in. machine is fed 200 tons of −0.5-mm. material and the sand discharge through a 9⁄16-in. spigot carries 83 per cent. water.

Pipe classifiers are pipe columns, usually vertical, fed through a branch fitting (Y or tee) let into the column. They make but two products, *viz.*: an overflow and one spigot product. A hindered-settling form was used at Bunker Hill and Sullivan (*2 MM 443*) for treating jig-hutch product. Sizing-assay test of feed is given in Table 21. Feed of this character assaying 55 per cent. Pb was divided by the classifier into a spigot product assaying 77 per cent. Pb and over-

Table 21. Sizing-assay test of feed to pipe classifier at Bunker Hill & Sullivan Mg. Co.

flow containing 49 per cent. Feed from the second hutch of the jig, containing 25 per cent. Pb made a spigot product with 60 per cent. Pb and an overflow carrying 12 per cent.

4. Design of hydraulic classifiers

There are several cases to consider, *viz.:* (1) free-settling shallow-pocket launder type; (2) deep-pocket types; (3) tank types; (4) hindered-settling columns for any of the above. The first case involves design of the free-settling sorting column and the launder and consideration of the diameter of the spigot aperture; the second, that of a roughing pocket above the sorting column, whether the latter be free- or hindered-settling; the third, the design of the tank for removing slimes; the fourth, the relative areas of sorting column and teeter chamber.

Design of free-settling sorting column. The data required are: (1) tonnage of solid matter to be passed; (2) average size of all of the light-mineral grains that are to settle; (3) average diameter of the smallest light-mineral grains that are to settle. From Table 1 or from the proper formula (see Art. 1) determine the velocity of rising current necessary to raise all light-mineral grains smaller than (3) above and also the free-settling velocity of the average light-mineral grain. The difference between these two figures will give the average settling rate of the light-mineral particles. The volume of the tonnage to be passed per unit of time, reckoning all solid as having the specific gravity of the light-mineral, divided by the resultant falling velocity of the average grain, gives the average solid cross-section of the falling stream of solids. The area of the sorting column should be made about 50 per cent. more than this to allow for voids in the mass of settling grains. This allowance, plus the additional allowance that is inherent in the calculation because of the less volume and higher falling velocities of the heavy-mineral grains is sufficient.

Launder slope and size must be sufficient to cause the material to travel between sorting columns with the water available. General data on launder slopes are given in Sec. 20. Normally a slope between ½ and 1 in. per ft. will be sufficient.

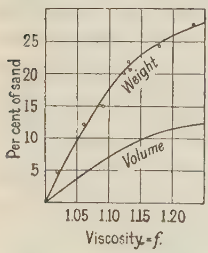

FIG. 25.—Relation between pulp consistency and viscosity (*after Richards and Dudley.*)

Spigot diameter, effective head on spigot, size of particles to be discharged and moisture content of spigot product are interrelated.

Flow of sandy pulps through pipe-and-plug spigots is different from that of water by reason of friction of the solid particles against the walls and inner friction of the mass. Richards and Dudley (*51 A 398*) call the sum of these effects the viscosity of the pulp and give the curves shown in Fig. 25 for determination of this factor, f. These curves are the result of experimental work with a silicious sand (sp. gr. = 2.72) ranging in size from about 0.1- to 1.4-mm. The experimenters used this value in the following formula derived from the fundamental hydraulic-flow equation:

$$Q = Ac\sqrt{2gh}/f, \qquad (12)$$

where Q = volume discharged, A = area of spigot opening, c is a coefficient of discharge depending on the shape of the orifice, ranging from 0.85 to 0.95 for ordinary pipe-and-plug spigots, g is the acceleration due to gravity and h

the head on the orifice. They give the following example of the use of the formula:

Example: Required the size of opening to discharge 40 tons of sand (0.1- to 1.4-mm. sp. gr. = 2.81) per 24 hr. as a pulp containing 25 per cent. solids through a pipe-and-plug spigot with conical receiving end under a head of 3 ft. The percentage of sand by volume is the governing factor in this case and is 10.6. From Fig. 25, f for this pulp is 1.17. Using c.g.s. units and substituting known quantities in equation (12)

$$A = \frac{1.17 \times 1430}{0.88\sqrt{2 \times 980 \times 914}} = 1.42 \text{ sq. cm.}$$

and the diameter of the spigot = 1.35 cm. = 0.53 in. For coarser sands, higher values of f must be used and *vice versa*. With sand of the size and sp. gr. experimented with the maximum volume percentage that could be continuously discharged without clogging was 13.

The spigot aperture should be as large as is consistent with the head and the volume of material to be passed. The limiting lower diameter is theoretically 3- to 5-times the diameter of the largest particle passing (see Sec. 20) but this factor rarely enters on account of the fact that tonnage requirements demand a larger opening.

Design of roughing pocket is the same for both free-and hindered-settling classifiers. The fundamental principle is that the rising velocity across the area $x\,y$ (Fig. 26) should be the same as that in the free-settling column below. The volume moving past this section is that of the incoming pulp plus the added rising water less that of all previously settled solid. It is wise to keep the section $x-y$ as nearly square as possible in order to reduce eddying. The slope of the sides of the pocket should be between 60 and 75° from the horizontal, the steeper the better, in order to prevent sands from banking. If banking occurs the work of the column will be disarranged every time the bank caves and this will be a frequent occurrence unless the feed is extraordinarily regular. Steepness of slope must be balanced against resulting loss of head room.

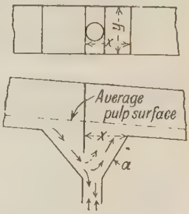

FIG. 26.—Roughing pocket.

Design of classifier tank is the same for both free- and hindered-settling machines. The tank is fundamentally a deep pocket for roughing out slimes and is, therefore, calculated to have a surface area such that the velocity of the rising current across the horizontal section at the level of the overflow lip will lift the coarsest particle that it is desired to overflow. The volume of rising current is the feed-pulp volume plus the total volume of hydraulic water rising in all sorting columns less the volumes of solid passing out of the spigots. The slope of the sides and discharge end should be at least 60° from the horizontal and better 70 to 75° to prevent banking. The feed end may slope as little as 45°, dependence being placed on the plunging effect of the incoming pulp to prevent banking here. The bottom slope should be 1½ to 3 in. per ft.; the greater slope gives greater capacity but tends to throw oversize into the later spigots. The sides of the tank necessarily flare toward the overflow end. Their slope is kept constant throughout the length. A safety spigot without rising current should be provided beyond the last hydraulic sorting column in order to discharge sand that is carried past this column but cannot be overflowed. This spigot may discharge continuously or intermittently according to the performance of the classifier. The product will be predominantly fine sand, but will contain considerable slime.

Design of hindered-settling column. The area of the constriction is determined in the same way as the area of a free-settling sorting column. The constriction may be a hole in a plate or at the bottom of a conical tube, if no rising current is to be employed, but with rising current a plurality of small holes is better than a single large one and experiments at ANACONDA (*46 A 266*) indicated that tubes a couple of inches in length tapped into a plate were better than a perforated plate or screen alone. The ratio of the area of the teeter chamber to the area of the constriction is important. Experiments at ANACONDA (*loc. cit.*) showed that for each size of grain there is a certain maximum density that can be maintained in the teeter chamber and yet permit discharge of solid through the constriction. If the ratio of the area of the teeter chamber to that of the constriction is too great, no sand can fall through the constriction when full teeter exists, and if the current is reduced to allow sand to fall, banking occurs in the teeter chamber and capacity is reduced; if the ratio is too small, teeter cannot be maintained but free settling will take place. The ANACONDA experiments indicated that the PERMISSIBLE DENSITY, meaning that co-existing at full teeter with free discharge through the constriction, varies inversely as the square root of the surface of a given weight of grains. The ratios of area of teeter chamber to area of constriction necessary to give the permissible density for different grain sizes may be read from Fig. 27.

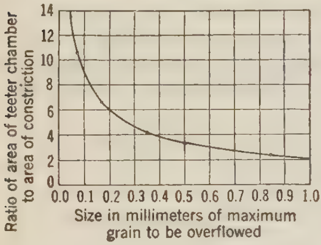

FIG. 27.—Ratio of areas of teeter chamber and constriction in a hindered-settling column.

Design of a hindered-settling tank classifier involves all of the elements of design of other types.

Example: To design such a machine with 4 spigots, to treat 200 tons per 24 hr. of −2.5-mm. feed in a pulp containing 25 per cent. solids, overflow −0.07-mm. material, and divide the sands into 4 products of such nature that the size range of the light-mineral particles will be the same in each spigot. Suppose that screen analysis of the material shows the following size-weight relations; −0.07-mm., 8 tons per 24 hr.; 0.07 to 0.68-mm., 72 tons; 0.68 to 1.29-mm., 56 tons; 1.29 to 1.90-mm., 32 tons; 1.90 to 2.5-mm., 32 tons.

To determine the constriction area for the first sorting column: the volume of solid to be passed per second, taking the sp. gr. of the light mineral at 2.6, = 4040 × 32 = 129,000 cu. mm. The mean diameter of the solids that are to settle = (1.90 + 2.50)/2 = 2.2 mm. The settling velocity of the mean particle = 178 mm. per sec. (From Table 1.) The settling velocity of the smallest particle = rising current to be supplied = 163 mm. per sec. The net falling velocity of the solid = 178 − 163 = 15 mm. per sec. The cross-section of the falling solid, considered as a solid bar, = 129,000/15 = 8600 sq. mm. The area of the constriction should be 1.5-times this area = 1.5 × 8600 = 12,900 sq. mm. In similar fashion the areas of the other constricted sections are found to be: column 2, 6680 sq. mm.; column 3, 14,100 sq. mm.; column 4, 11,030 sq. mm. If single pipes were to be used for the sorting column, 5-, 4-, 6- and 5-in. pipes respectively could be chosen. Most designers would furnish 5-in. pipes for the first two columns and 6-in. for the last two on account of greater simplicity in construction. The areas of teeter columns may be obtained by multiplying the constriction areas by the following factors taken from Fig. 27: No. 1, 1.5 (extrapolated); No. 2, 1.9; No. 3, 2.8; No. 4, 10.5; making the areas, on the basis of 5- and 6-in. sorting columns as above, 30, 38, 81 and 304 sq. in. respectively. The corresponding nearest standard pipe diameters are 6 in. 7 in., 10 in., and 20 in. The length of sorting column necessary increases with the size of material that is to be overflowed. Bardwell (*46 A 266*) states that 4 in. is sufficient for a de-slimer column and 8 in. for most cases. The area of the tank at the overflow level is computed to give a rising current of 4.1 mm. per sec. with the feed water plus the rising hydraulic water overflowing. The feed water is 600 tons per 24 hr. The volume of hydraulic water rising cannot be calculated accurately but may

be estimated with sufficient precision by assuming that 50 per cent. of the area of the constriction is unoccupied by solid. Under this assumption the available area in 5-in. standard pipe is 6450 sq. mm. and the volume rising, at 163 mm. per sec., is 1,050,000 cu. mm. per sec. The volumes from the other columns are 755,000, 642,000 and 38,200. The total overflow is 8,805,200 cu. mm. per sec. The required area = 8,805,200/4.1 = 2,140,000 sq. mm. = 23.2 sq. ft. A tank averaging about 2 to 2.5 ft. wide by 9 to 12 ft. in length is indicated. The depth of the tank and the size of spigot opening are interdependent. The first spigot must discharge 32 tons of solid per 24 hr. with, say, 96 tons of water. The determination of proper depth (head on discharge) and diameter of spigot is made by trial and error. Assume 4 ft. head. Then, from equation (12) (p. 580) the spigot diameter must be 1⅜ in. If a smaller spigot opening is desired the tank must be made larger and *vice versa*. The slope of the tank bottom should be at least 1½ in. per ft. and this slope, with the depth above the first spigot fixed, fixes the depth above the other spigots. From this depth the diameters of the other spigots may be computed.

5. De-sliming classifiers (non-mechanical)

Whole-current classifier is shown in Fig. 28. Pulp enters behind the perforated baffle (A) and is distributed in a series of streams, as indicated, across the transverse section of the classifier. In order that a particle may settle out of the stream it is necessary that it settle to the bottom before it is carried through the perforated baffle (B) at the discharge end. On the discharge side of baffle (B) the velocity of the rising current is $v = Q/xb$ and as x is less than l, all particles that failed to settle before reaching (B) will be readily lifted. If Q = the total volume of entering pulp; l, b and d = length, breadth and depth of the classifier respectively and H and V the horizontal and vertical resultant velocities, respectively, of a solid particle whose diameter is D and density δ, then d/V must be less than l/H for a particle to settle.

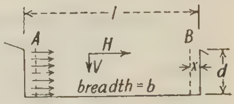

FIG. 28.—Whole-current classifier.

$$H = Q/bd, \qquad \qquad (13)$$

$$V = v_1 - v_2$$

where v_1 = the falling velocity of the particle in still water $= C\sqrt{D(\delta - 1)}$, and $v_2 = Q/bl$.

$$V = C\sqrt{D(\delta - 1)} - Q/bl. \qquad \qquad (14)$$

The limiting condition is when

$$\frac{d}{V} = \frac{l}{H} \qquad \qquad (15)$$

or

$$\frac{d}{C\sqrt{D(\delta - 1)} - Q/bl} = \frac{lbd}{Q} \qquad \qquad (16)$$

from which

$$D = \frac{4}{(\delta - 1)}\left(\frac{Q}{Clb}\right)^2 \qquad \qquad (17)$$

and

$$lb = \frac{2Q}{C\sqrt{D(\delta - 1)}} = \frac{2Q}{v_1}. \qquad \qquad (18)$$

It will be noted from equation (17) that the size of particle that can be separated in a given whole-current classifier is independent of the depth and of the relative proportions between length and breadth.

For particles below the "critical size" (Art. 1)

$$v_1 = KD^2(\delta - 1) \qquad \text{By equation (2).}$$

Then

$$V = KD^2(\delta - 1) - \frac{Q}{lb} \quad . \ . \ . \ . \ . \ . \ . \ . \ . \quad (19)$$

$$D = \sqrt{\frac{2Q}{blK(\delta - 1)}} \quad . \ . \ . \ . \ . \ . \ . \ . \ . \ . \quad (20)$$

and

$$bl = \frac{2Q}{KD^2(\delta - 1)} = \frac{2Q}{v_1}. \quad . \ . \ . \ . \ . \ . \ . \ . \quad (21)$$

Whole-current classifiers are rarely used for the reason that they require more floor space for a given duty than do surface-current machines, as will appear below.

Sloughing-off boxes or V-boxes are the commonest form of whole-current classifier at the present time. They consist of a V-shaped box, with sides sloping 50 to 60° from the horizontal, 10 to 50 ft. long and 4 to 8 ft. deep. They are usually without partitions, but are discharged by means of spigots or goose-necks at several points along the length. Their principal use is as dewaterers and de-slimers where clear overflow or clean sand is not essential. Table 22 (*1 OD 463*) gives sizing tests of the combined spigot product and overflow of a 4-spigot tank 4 ft. deep by 17 ft. long.

Table 22. Performance of a 4-spigot V-box

−0.07	62.2	100.0

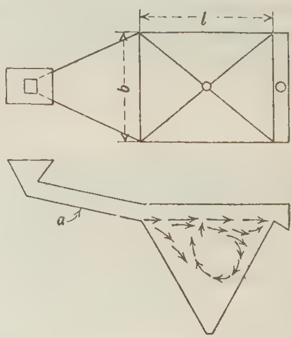

FIG. 29.—Surface-current classifier.

Surface-current classifier is shown diagrammatically in Fig. 29. Pulp enters over the feed sole (*a*) at the same level as the overflow. There is a distinct surface current toward the overflow lip, as indicated, but there are also many eddies of the general character indicated. Solid particles that fall out of the surface stream must settle against the rising current, which, while it varies from point to point over any horizontal section and may even be negative (*i.e.*, downward) at some points, nevertheless has an average upward velocity

$$v = Q/lb. \quad . \ . \ . \ . \ . \ . \ . \ . \ . \ . \quad (22)$$

If v_1 is the settling velocity of a given particle, v_1 must be greater than v in order for the particle to appear in the spigot product.

For particles larger than the critical size (Art. 1) $v_1 = C\sqrt{D(\delta - 1)}$ (Art. 1, Eq. 4). In the limiting case $v = v_1$, hence

$$C\sqrt{D(\delta - 1)} = Q/bl \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad (23)$$

from which

$$D = \frac{1}{\delta - 1}\left(\frac{Q}{Cbl}\right)^2 \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad (24)$$

and

$$bl = \frac{Q}{C\sqrt{D(\delta - 1)}}. \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad (25)$$

For particles below the critical size:

$$D = \sqrt{\frac{Q}{blK(\delta - 1)}} \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad (26)$$

and

$$bl = \frac{Q}{KD^2(\delta - 1)}. \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad (27)$$

Comparing equations (24) and (26) with equations (17) and (20) it will be seen that finer particles can be settled in a surface-current classifier of given horizontal cross-section than in a whole-current machine, and conversely, by comparing equations (25) and (27) with (18) and (21), to settle particles of a given size the surface-current classifier requires but half the surface area of the whole-current apparatus.

Rittinger spitzkasten is the typical form of surface-current classifier without hydraulic water. It consists of a series of pointed boxes, similar to Fig. 29, increasing in depth and area toward the discharge end. *Rittinger* recommended that the first box be made about one inch wide for each cubic foot of pulp fed per minute and that the width of each succeeding box be twice that of the preceding. For 20 cu. ft. of pulp per min. he recommended lengths of 6, 9, 12 and 15 ft. respectively for 4 boxes. The sides should slope at least 50° and better 60° from the horizontal. Slopes of the connecting launders should be: about ¼ in. per ft. for the feed launder, ⅛ in. per ft. from the first to the second box, $\frac{1}{16}$ in. per ft. from the second to the third, and $\frac{1}{32}$ in. per ft. from the third to the fourth. Richards' experiments (*27 A 249*) indicate that the feed sole should slope about 5° from the horizontal and should enter on the same level as the overflow. The overflow should be level. Eddying will invariably cause much slime to enter the spigot products. Discharge of coarse material is made through pipe-and-plug spigots at the apex of the box; fine material is discharged through goose-necks. In some cases successive boxes are joined so that the upper edge of the division wall is below the overflow level as in Fig. 17 and no connecting launders are needed.

a Baffle plate in second box to direct current downward.

Performance of a 2-box machine treating lead ore, the overflow from a hydraulic classifier, is given in Table 23 (*1 OD 462*).

Spitzkasten with hydraulic water are used in some Joplin zinc mills to prepare feed for table concentration. Table 24 (*57 A 453*) gives results of the operation of a 9-box classifier of this type.

Callow tank (Fig. 30) has the form of an inverted cone with 60° apex angle. It is used either for de-sliming or dewatering. The principle is the same as that of all rising-current free-settling classifiers. Success has been due to simplicity and excellence of design. The overflow rim is a cylindrical steel band, cleated at intervals to the cone wall near the top, the joint made tight by first packing with oakum then pouring in a thin cement grout. An endless rubber belt stretched tightly around the metal band is readily leveled, after the tank is full, by tapping with a wooden mallet. Spigot discharge is effected through a bushing or plug cock at the apex or by a goose-neck siphon. Feed is introduced at the center through a pipe 5 to 12 in. diameter projecting 6 to 10 in. below the overflow level. The rating is based on the diameter of the overflow band. Weight varies from 165 lb. for the 2-ft. size to 650 lb. for the 8-ft.; rated capacity of the 2-ft. cone in de-sliming service is 24 tons per 24 hr.; 4-ft., 100 tons; 8-ft., 400 tons: in slime dewatering, 4-ft., 6 to 8 tons; 6-ft., 14 to 18 tons; 8-ft., 25 to 30 tons.

Performance. At Tonapah Belmont Development Co. 5-ft. Callow cones handle 70 tons solid per 24 hr. in a pulp containing 85 per cent. moisture. The spigot product contains 79 per cent. moisture and the overflow 87 per cent. Screen tests of feed and products are given in Table 25. At United Eastern (*63 A 554*) Dorr-classifier overflow

was sent tô 8-ft. Callow cones. The feed to each cone ranged from 16 tons solid and 1100 tons cyanide solution to 213 tons solid and 970 tons solution (87.3 and 82 per cent. solids respectively) per 24 hr. Spigot discharge was through a 1.5-in. goose-neck fitting 30 in. below the cone overflow. The spigot product at the maximum solid-feed rate given was 73 tons solid and 83 tons solution (54 per cent. moisture); overflow, 140 tons solid, 884 tons solution (86.3 per cent. moisture). Sizing tests of products are given in Table 26. Performance in dewatering service is given in Sec. 16, Art. 5.

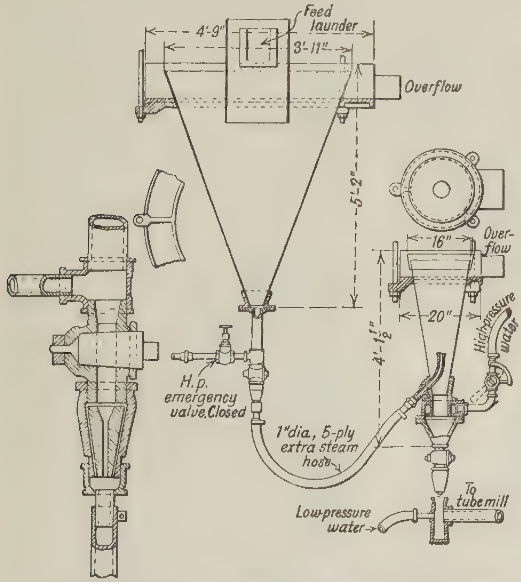

FIG. 31.—Series classification in cones at Homestake.

Homestake method of series classification in cones (*22 IMM 90*) is shown in Fig. 31. Feed enters the larger cone, which is run with a small discharge bushing so as to overflow about 88 per cent. of the total solids. The small cone re-works the spigot product of the first. Sizing-assay tests of products are given in Table 27.

Hindered-discharge cones

The difficulty in maintaining a continuous discharge of thick sandy pulps from settling tanks has led to several expedients. The first and most obvious

was intermittent manual discharge of the spigot product, allowing time between discharges for the coarser material to build up to a considerable depth and squeeze out water and suspended slime. This method was succeeded by a mechanically-operated intermittent slush gate. The Caldecott diaphragm in a steep-sided cone was the first successful device for continuous discharge of thickened sand. It was followed by the Allen cone, and Boylan and Wood classifiers, all of which are conical or pyramidal tanks with intermittent discharge automatically controlled.

Caldecott cone (Fig. 32) consists of a sheet-iron conical tank, with apex angle not more than 60° for coarse feed and about 40° for fine, having a disk-diaphragm near the apex, so supported as to leave an annular space between its edge and the cone wall. The cone is center-fed through an inlet pipe 6 to 8 in. diameter, carrying a disk-shaped baffle a few inches below the lower end. The area of exit between pipe and baffle should exceed the area of the pipe. The feed pipe should project 12 to 18 in. below the overflow level. The lower end of the cone wears most rapidly and is usually a hard-iron casting with removable bushings. It is fitted with an easily replaced sliding gate by means of which the flow can be regulated. The velocity of the rising current is predetermined within a certain range by means of the cylindrical sheet-iron ring surrounding the feed pipe. This fixes the maximum cross-section of the rising current. In operation the cone is allowed to fill with sand to a height about 2 ft. below the overflow lip at the center and extending nearly or quite to the overflow level at the periphery. The usual dimensions of the cone are 6 ft. diameter by 9 ft. deep and 8 ft. diameter by 10 ft. deep. The size and placing of the diaphragm are matters of experiment. With sandy feed the diaphragm is placed 12 to 18 in. above the spigot opening and the width of the annular opening is 0.75 to 2 in., the larger figure for finer material. For finest sand and slime the annular opening must be larger, in order to prevent bridging of thickened material. It is made 3 to 6 in. across, and the diaphragm must, therefore, be carried somewhat higher in the cone. Fig. 32 shows a double diaphragm for treating fine material.

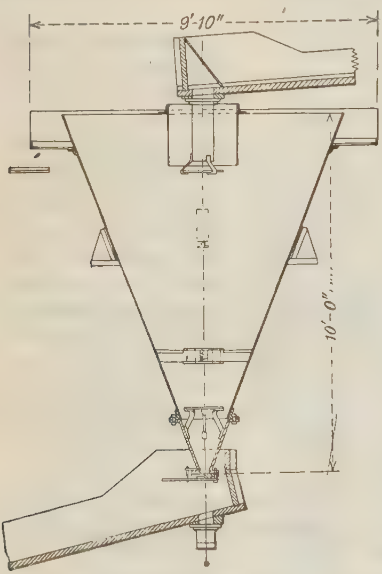

Fig. 32.—Caldecott cone with double diaphragm.

The purposes of the diaphragm are to slow down the flow of sand toward and through the spigot, and to prevent center-piping and bridging. Bridging cannot occur at the spigot because of the direction from which the solids approach, *i.e.*, obliquely convergent down the walls of the cone from the periphery of the diaphragm. Center-piping is prevented by the intervention of the diaphragm across the axis of the possible pipe. This eliminates rapid

settling and discharge of coarse material, which is the cause of piping in ordinary cones. Discharge through the spigot is slowed down by decrease in pressure effected by friction losses in the annular space surrounding the diaphragm, and the rate of approach to the spigot is limited at the same time by the same phenomenon.

The action in a diaphragm cone is substantially free settling with both horizontal and vertical currents. The construction of the feed pipe is such that the pulp stream starts flowing horizontally in all directions. Heavy, coarse sand is dropped near the center and finer sand near the periphery. With all conditions constant the surface of the settled solid stabilizes in such a position that the rising velocity in the annular section at the overflow level is just sufficient to lift the coarsest overflow particle, and settled solid is withdrawn through the spigot at a rate just equal to that of deposition.

Sizes and moisture content of the products relative to size and moisture content of the feed are affected by change in rate and character of feed and in size of spigot opening. If the size of particles and tonnage of solid matter in the feed remain constant, change in the amount of water sent to the classifier will not permanently affect either the size of products or the moisture content of the spigot discharge. Increase in quantity of feed water will cause instant increase in rising velocity of the overflow pulp with consequent scour of the sands, until the velocity over the increased cross-section is the same as it was before the change, when deposition and spigot discharge will again proceed at equal rates. Decrease in quantity of feed water will cause deposition and constriction of the overflow stream until deposition and spigot discharge again equalize. Decrease in size of feed particles without change in pulp volume will result in lessened deposition and, if discharge continues at the same rate, lowering of the sand surface and increase in cross-section of overflow stream. This will result in lessened velocity of the overflow stream and increased deposition until deposition and discharge rates equalize. At this time, since finer material is depositing, finer will also overflow. Similar reasoning shows that coarser feed will produce coarser overflow and coarser spigot product. The moisture content of the spigot discharge is dependent largely upon the percentage of voids in the settled solids, when packed as tightly as they will pack under the conditions of settlement. Coarse material has less voids than fine, hence less moisture; material containing particles of considerable range of sizes has less voids than that closely sized and hence less moisture. Concurrent change of moisture content and tonnage and/or size of feed particles may completely change the character of the discharge through a given spigot. Thus concurrent decrease in moisture content and solid tonnage will lessen overflow velocity and tend to cause deposition of finer material. At the same time the surface of the settled solids will lower by reason of excess of discharge over deposition, overflow velocity will be further reduced and yet finer material deposited. Assuming ultimate equalization of deposition and discharge, stabilization will occur with a large increase in the amount of fines depositing, and there will be corresponding increase in the fineness of both spigot and overflow products. The result, as concerns moisture content of the spigot product, cannot be predicted accurately; the greater size range will tend toward less moisture and the finer size toward more. It should be noted also, in this analysis, that if the reduction in moisture content is sufficiently great and there is enough fine solid present to produce a suspension that acts like a liquid of high specific gravity, the carrying power of the overflow may be sufficient to lift coarse material, and if the spigot is changed to prevent lowering

of the sand level, the size of the products and the moisture content of the spigot discharge may be maintained unchanged. When the water content of the feed decreases and solid tonnage increases, the respective effects are conflicting; the volume passing may increase or decrease, the carrying power of the current may increase by reason of an increase in specific gravity, and the sand level may either raise or lower, if the spigot size is maintained. The probable result is coarser overflow and an increased tonnage of coarser sand with slight decrease in moisture content. Concurrent decrease in moisture content and size of feed will usually result in marked decrease in size of spigot product and overflow, although, owing to increased apparent density of the overflow pulp, it may be possible to keep the overflow size up by decreasing the spigot opening. All other things remaining constant, increase in spigot opening will give finer products and *vice versa*. Since the spigot opening is ordinarily the only variable in control of the operator he thereby compensates for changes in quality and quantity of feed.

Performance. The Caldecott cone has had its greatest development in Rand gold mills, where it has been used to guard tube-mill discharge and return sands for re-grinding. In this service an 8-ft. cone will discharge 400 to 600 tons of +90-mesh (0.006-in.) quartzitic sand per 24 hr. in a pulp containing about 30 per cent. moisture when the feed contains about 40 to 50 per cent. of −90-mesh slime.

Results with an 8-ft. double-diaphragm cone at SIMMER AND JACK are given in Table 28. At a Mexican mill (*10 JCM 287*) a cone 4 ft. 10. in. deep by 4 ft. diam. fitted with a diaphragm 8 in. from the apex, leaving 1.5-in. annular space, was fed at 240 tons per 24 hr. Results are given in Table 29. At the ST. JOSEPH LEAD CO. Bonne Terre mill (*57 A 432*) a 6-ft. Caldecott cone handled 400 to 500 tons of −2-mm. sand tailing per 24 hr., made an overflow containing no material coarser than 0.1-mm., while the spigot product averaged 28 per cent. moisture. The sand level was held about 2 ft. below the overflow. A sizing test of the spigot product is given in Table 30. Mixed jig and table galena concentrate was discharged from a 6-ft. cone with 11 per cent. moisture, but intermittent discharge was necessary on account of the variable feed rate.

Automatic diaphragm cone used at Mt. Lyell (*38 Aa 109*) is shown in Fig. 33. With no sand in the cone, the counterweight closes the spigot valve. When settled sand rises to the cylinder on the plug rod the drag of the sand pulls the cylinder down and opens the valve. Performance is shown in Table 31.

Another automatic-discharge device is shown in Fig. 34 (*22 JCM 74*). The counterweight is set to discharge the proper tonnage at the desired percentage of moisture. If the pulp thins down, the velocity of discharge increases, with resultant increase in friction and pressure on the valve plug and the valve closes somewhat, thus retarding discharge and permitting solids to build up again. The device gave satisfaction at FERREIRA DEEP mill on tube-mill cones as compared with manual regulation of standard Caldecott cones. The normal moisture content of spigot product was 25 per cent. and a sizing test showed 57 per cent. +60-mesh, 33 per cent. +90-mesh and 10 per cent. −90-mesh.

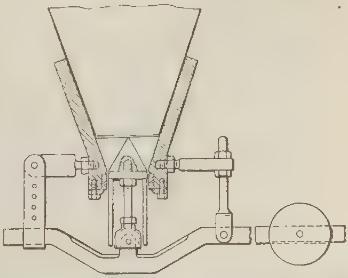

FIG. 34.—Automatic diaphragm cone.

Allen cone (Fig. 35) consists of a conical sheet-iron tank, center-fed, with peripheral overflow of slime and automatic regulation of sand discharge.

The spigot regulator consists of a spring-controlled link mechanism actuated by a float (F). Feed entering the center pipe (A) is distributed by the baffle (B), flows into the tank proper, the sand settles out and slime overflows the lip (L). When the upper surface of the settled sand reaches the position shown in the sketch, water backs up in chamber (C), float (F) is lifted, the valve rod is depressed and the ball valve (J) opened. Resistance to opening is varied by the weight (K). The valve seat is carried on a swinging plate, so arranged that when the spigot opening is swung to one side for inspection or replacement, the lower end of the cone is closed by a blank plate. New spigot liners can be dropped into place quickly, thus making it unnecessary to shut down. The cross-section of the overflow may be lessened by introducing a REDUCTION RING (R), which increases the rising velocity and consequently increases the size of particles overflowed. The effect is shown in Table 32. A diaphragm (D) is used to reduce the percentage of moisture in the sand discharge and to regulate the flow of solids. Standard sizes are given in Table 33.

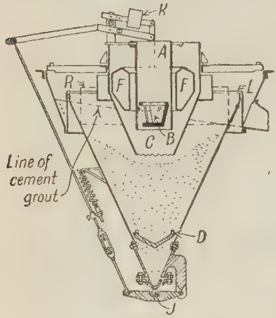

FIG. 35.—Allen cone.

40–3	8′ 0″	9′ 11″	1600

Performances are given in Table 34. Delano (*57 A 440*) says that a 6-ft. cone will treat galena concentrate ranging from 9-mm. down to 5 or 6 per cent. −200-mesh and carrying 83 per cent. water at the rate of 100 tons per 24 hr., make a spigot discharge containing 12 per cent. moisture and yield a clear-water overflow. On tailing ranging from 2-mm. to 0.1-mm. the same cone will treat 300 tons per 24 hr., yielding a spigot product containing 28 per cent. moisture and a clear overflow. He states that sand coarser than

3-mm. would be difficult to dewater unless it contained a large percentage of fines. Watt (*57 A 440*) says that a 4.5-ft. cone will handle 145 tons per 24 hr. of the undersize of a 10-mm. screen, yielding a spigot product containing 28 to 30 per cent. moisture and with less than 3 per cent. coarser than 200-mesh in the overflow solids.

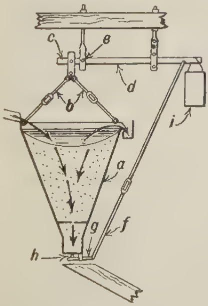

Fig. 36.—Boylan automatic cone.

Boylan automatic cone classifier (Fig. 36) consists of a conical or pyramidal tank (*a*) suspended by rods (*b*) from a knife edge on the short end (*c*) of lever (*d*). This lever is suspended at (*e*). The long arm connects by means of rod (*f*) to a short lever (*g*) whose fulcrum is carried on the lower part of the tank. The working arm of lever (*g*) carries a conical valve (*h*). Feed is introduced at the top at one side, sand settles out and slime overflows on the opposite side. When sufficient sand (about 60 to 75 per cent. of the volume of the tank) has collected, the weight of the tank causes rod (*f*) to be lifted, thus opening the valve (*h*) and permitting discharge of sand. The tripping point is determined by weights (*i*).

Wood automatic classifier (Fig. 37) (*114 J 351*) consists of a pyramidal tank (1) hung by means of straps (4) and suspension rods (6) on knife-edge bearings (8) on the short arms of levers (5). The fulcrums of these levers at (9) are knife edges that support the entire mechanism. The long arms of the levers (5) are attached through a vertical connecting rod (10) to another lever (13) whose fulcrum (14) is mounted on the lower end of the hopper and whose working end carries a conical plug valve (15).

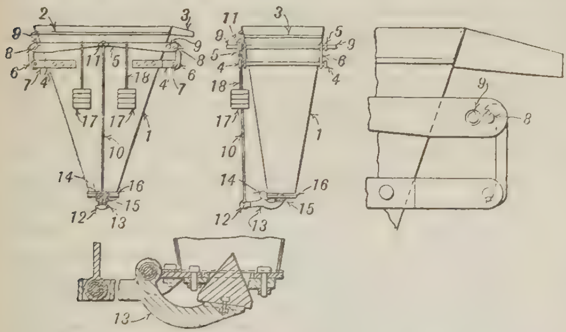

Fig. 37.—Wood automatic sand-slime separator.

When the cone lowers under the load of settled sand, (10) is lifted and the valve opened. Feed is introduced at (2) and slime overflows at (3). Rate of discharge is regulated by the position of the weights (17). Detail of the apex is shown in the large-scale figure. The inventor claims efficiencies of 70 to 90 per cent. with from 25 to 40 per cent. of moisture in the sand discharge.

A cleaner sand discharge and coarser slime overflow can be obtained in tank separators if gentle agitation is maintained in the settling zone.

At the Le Roi No. 2 mill, Rossland, B. C. (*114 J 1121*) a de-sliming cone was used to close the grinding circuit on a secondary ball mill; a short air-lift kept the upper part of the contents in gentle circulation. The degree of agitation was varied by vertical adjustment of the air-lift riser and by variation of air pressure.

6. Mechanical classifiers

Dorr classifier (Fig. 38) consists essentially of a rectangular tank (*a*) with sloping bottom, closed at the lower end by means of a vertical end wall (*b*), open at the upper end, and having suspended therein a mechanically-operated raking mechanism (*c*). The rakes are suspended by links (*d*) and (*e*) from arms of cranks (*f*) and (*g*) respectively. The pin of crank (*g*) is attached to the main frame of the apparatus, the pin of crank (*f*) is mounted on the arm of crank (*j*), whose position is regulated by means of the rope (*k*) and the drum (*l*), actuated by worm gear from crank (*m*). Power applied

to pulley (n) is transmitted by a pinion and gear to cam (p). The latter, working against roller (q) on the downwardly extending arm of crank (g) causes the arm of this crank to be raised and lowered and with it the upper end of the rakes. Simultaneously the arm of crank (f) is raised and lowered through connecting rod (r), similarly moving the lower end of the rakes. Coincident with the raising of the rakes, a crank attached to the shaft of cam (p) transmits motion through connecting rod (t) to the rakes in a plane parallel to the inclined bottom and directed down slope. Further revolution of the cam into the position shown in the figure causes the rakes to be dropped to the lowest position and in this position the rakes are dragged up slope.

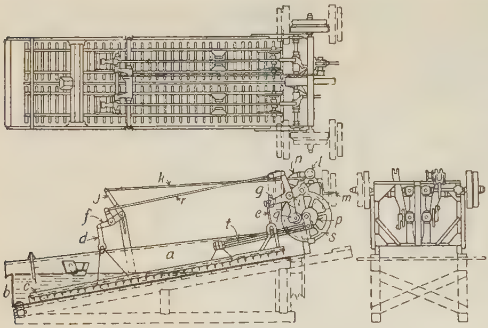

Fig. 38.—Dorr duplex classifier.

Classifiers are rated by giving the width of tank and the nominal length of the inclined bottom and are called simplex, duplex or quadruplex according to whether one, two or four sets of rakes are operated in the same tank.

Classifiers are made with tanks 2 ft. 3 in., 4 ft. 6 in. and 6 ft. wide, with one set of rakes in the narrowest tank, and two sets side-by-side in the wider tanks, driven from the same mechanism. The usual form is the two-rake or duplex type. The simplex type is used for small capacities. A special quadruplex form has been used at Calumet and Hecla for dewatering sand tailing, where handling the sand was the important feature and great raking capacity was necessary. The 4-ft. 6-in. duplex is designated "Model C"; the 6-ft., "Model D" machine, is of much heavier construction throughout and is to be recommended where large tonnages of sand must be handled.

The classifying action of the apparatus is the result of currents set up by the movement of the rakes and by the entrance and flow of liquid pulp through the machine. The rake movement and the plunge of the entering stream stir the pulp sufficiently to keep the smaller granular particles in suspension. The general flow of liquid through the settling basin to and over the overflow lip and the surge of pulp incident upon the movement of the rakes carry the suspended particles out of the machine. The more vigorous the stirring, the larger the particles prevented from settling; the greater the carrying power of the overflowing stream, the larger the particles overflowed. The factors affecting suspending and carrying power are: speed of rakes, slope of bottom, height of tail board, height of rakes, placing of baffle, volume of pulp, character of ore, pulp dilution, and size of solid particles. The character of the sand discharge is affected primarily by the character of the overflow, a fine overflow resulting in much fine material in the sand and *vice versa*. It is affected independently by the length of the bottom, slope of the bottom and quantity of wash or back water employed.

Slope of bottom together with height of tail board determine the area of the settling pond and therefore the average rising velocity of the pulp stream. These also determine the volume of the settling pond and consequently the vigor of the stirring effected by a given rake movement. Slope also affects performance by determining, to a considerable extent, the composition of the body of pulp remaining in the classifier at all times. With

steep slope the ratio of downward travel to upward travel of any given grain along the bottom for one cycle of the rakes is greater than with a flat slope because of the difficulty of holding sand grains, particularly the small ones, on the steep incline. Consequently the grains in the body of pulp in the settling pond are coarser with steep slope than with flat slope. This produces a coarser overflow, since grains that cannot discharge with the sands must discharge with the overflow, if the classifier is to continue to operate. Steep slope also, therefore, produces a coarser sand discharge than flat slope. Slopes range in mill practice from 1.5 in. per ft. for 200-mesh separation to 3 in. per ft. for 48-mesh separation. The Dorr Co. recommends even steeper slopes for 28-mesh separation. When a large tonnage of sand is to be separated from a comparatively small amount of slime, low slope may be employed to give a large settling pond, with high rake speed to move the settled sand and high dilution (small percentage of solids) in order to permit quick settlement of solids. Column 9, Table 40 shows this combination. Comparison of columns 3 and 8 shows how a larger tonnage may be handled without change in products by flattening the slope of classifier bottom.

Height of tail board should be such that with the bottom slope employed, a pond of sufficient size will be formed to allow settlement of all sand coarser than that which is to be overflowed and the pond should be of such depth that eddies and surging caused by the agitation will not throw coarse sand into the overflow. The standard depth in mill-size classifiers is from 21 to 24 inches. Increase in depth results in larger settling area and lessening of the surface agitation due to rake movement and pulp inflow, with the result that the overflow is finer (see Table 36) and more fine material is discharged with the sands. Table 38, however, shows that the effect is not great. (Columns 1 *vs.* 3 and 2 *vs.* 4.) If the same character of overflow can be taken as before the change, then greater tonnage can be handled with a higher tail board although usually at the expense of a higher water and slime content in the sand discharge. When the specific gravity of the solids is high, the tail board must be lower than with normal ores.

Table 36. Effect of height of tailboard on overflow product of Dorr classifier

Screen aperture, mesh	Weight, cumulative per cent.	
	Standard height of tailboard	Tailboard raised 4 in.
60	0.2	0.5
80	2.5	1.4
100	7.6	5.2
150	24.8	22.5
200	38.3	32.8
−200	61.7	67.2

Height of rakes. Raising the rakes decreases the effective depth of the settling pond, and increases the agitation near the surface. The result is to keep coarser sand in suspension and so produce a coarser overflow.

Length of classifier depends partly upon structural demands and partly upon the character of sand discharge desired. Where the classifier is to be operated in closed circuit with a grinding mill it is depended upon to elevate the sand return to a point that will allow this material to flow by gravity into the mill feed box. In such cases it may be necessary to lengthen the classifier beyond the point required for classification alone. Generally from 5 to 6 ft. of unsubmerged bottom or draining space is the minimum allowed where a sand product containing 20 to 25 per cent. moisture is desired. If less moisture is wanted in the sand a longer draining space or use of a dewatering lip is necessary.

Dewatering lip consists of a prolongation of the floor of the classifier at the sand-discharge end for about 6 in. on a slope of 30 to 45° with the horizontal. By making the discharging sands climb this additional slope, a considerable reduction in moisture can be attained.

Speed of rakes is determined by the number of strokes per minute and the length of stroke, and since the length of stroke in mill-size classifiers is usually fixed at 12 to 15 in., speed variation is effected by changing the number of strokes per min. Speed has several effects on performance.

(1) It affects the degree of agitation of the pulp in the settling pond and thereby determines the size of particles that can be kept in suspension. This in turn affects the size of overflow particles, since particles that cannot settle must overflow, if the classifier is to continue to operate. The specific gravity and viscosity of the fluid pulp are likewise increased by increased agitation. This results in increased suspending and carrying power of the overflow current.

(2) Speed affects the velocity of the overflowing current. The average rising velocity of the pulp current is determined by dividing the volume of overflowing pulp per unit of time by the surface area of the settling pond but the actual rising velocity effective to lift out suspended solid is much greater than the average, due to surge toward the overflow lip caused by the return rake movement. The velocity of this surge current is proportional to the speed of the rakes. The usual speeds vary from 12 strokes per min. for 200-mesh

separation to 30 strokes per min. for 28-mesh separation. The effect of speed change is greatest when the speed is already near the maximum allowable for a given separation. Thus Table 37 indicates an appreciable increase in size of products due to increase from

Table 37. Effect of speed change on Dorr-classifier performance

Screen aperture, mesh	Weights, cumulative per cent.			
	20 strokes per minute		12.5 strokes per minute	
	Sand	Overflow	Sand	Overflow
On 60	42.9	....	42.9	....
100	72.1	1.2	67.9	0.1
150	89.3	2.6	74.8	0.9
200	92.0	14.0	87.0	6.3
−200	8.0	86.0	13.0	93.7

12.5 to 20 strokes per min. when 100-mesh separation is being carried on while Table 38, columns 1 *vs.* 2 and 3 *vs.* 4 show inappreciable effects for changes in the same speed range at 20-mesh separation.

Shape of rakes. Rakes are commonly made of structual angles, but flat rakes made of flat strap clipped to the underside of the rake channel are used when it is desired to lessen agitation in the settling pond. Notched rakes, made by staggering 3-in. rectangular cut-outs taken from the vertical flanges of the angles are used to decrease the water and slime in the sand discharge by permitting freer drainage. Columns 5 and 6, Table 38, show the effect on size. One or two top rakes placed above the channels near the point that these emerge from the settling pond may be used to give additional agitation at this place and produce cleaner sand. Raking capacity can be increased by increasing the depth of the vertical blade.

Baffle. The position of the baffle at the overflow end determines the cross-sectional area of the overflowing stream and thereby the velocity, all other things being constant. The position of the baffle can in no way influence the size of particles suspended by the stirring of the rakes, but by moving the baffle close to the tail board it is possible to lift out particles that otherwise might not be discharged but would build up in the pond until the classifier stalled or the density increased sufficiently to carry them over.

Volume of pulp. In a given classifier, change in volume of pulp changes the velocity of the overflow current proportionately. If change in volume is not accompanied by change in specific gravity of the pulp in the settling pond, *e.g.*, if the tonnage of pulp only is changed, increase will produce coarser products and *vice versa*. If, however, increase in volume is gained by increasing the water fed without corresponding increase in solids, the carrying power of the pulp is lessened on account of the decrease in specific gravity and viscosity and the result is likely to be a net decrease in carrying power and consequently in average size of products. (See also paragraph on *Pulp dilution*.) When, however, coarse-mesh separation is being made, changes of as much as 10 per cent. in the volume of pulp passing, without material change in dilution, have no substantial effect on the size of the overflow particles. (See Table 38.)

Dilution of pulp is the most important operating variable. Together with speed of rakes, character of ore, and fineness of feed particles, it determines both the specific gravity and viscosity of the pulp in the settling pond and it is the only one of these factors in direct control of the operator. The specific gravity of the fluid in which settlement occurs enters as ρ in the quantity $(\sigma - \rho)/\rho$ in the equation for velocity of fall of bodies in resistant fluids (turbulent resistance). (Art. 1.) Hence increase in ρ causes decrease in settling velocity, which means that larger particles are lifted by a given current velocity. Viscosity of the fluid enters in the denominator of the settling equations, hence increase in viscosity likewise causes overflow of larger particles.

With normal ores the specific gravity and viscosity of pulps are not greatly affected by changes in the percentage of solids when the percentage is less than fifteen. Below this figure decrease in density with corresponding increase in current velocity may cause coarser overflow. Above this point the effect of changes in dilution is marked and satisfactory control of classifier products can be effected by control of dilution. Columns 5 and 15, Table 40, show this clearly. Comparison of columns 13 and 16 shows the same thing, although here increase in moisture content of overflow is accompanied by decrease in solid tonnage, which also tends to produce finer overflow. With ores containing large amounts of semi-collodial material, viscosity is considerably affected by even less than

15 per cent. of solids and with such ores some variation in classifier products can be effected by dilution control even in dilute pulps.

Viscosity of the overflow stream has much greater effect on carrying power than either velocity or specific gravity. In the performances recorded in Table 39 the same tonnage of solid was treated in both runs. In the first run the volume of pulp passing through the machine was 2.25 times that in the second with correspondingly greater rising velocity. Notwithstanding the increased current velocity in the first run the product was markedly finer than in the second. The coarser product in the second run was due in small part only to the greater specific gravity of the pulps. For since V_D/V_T varies as $\rho_T(\sigma - \rho_D)/\rho_D(\sigma - \rho_T)$ it follows that on this score alone, the falling velocity of particles in the dilute pulp (V_D) is 1.18-times greater than the falling velocity of the same particles in a thick pulp (V_T) or that a rising velocity of dilute pulp 1.18-times as great as that of the thick pulp would overflow the same size particles. But since with a rising velocity of dilute pulp 2.25 times that of the thick pulp the particles lifted were smaller, it follows that the actuating cause was something other than the relative velocities or specific gravities of the pulps. Viscosity is the only remaining element in the settling equations to account for the difference in behavior. V_D/V_T varies as μ_T/μ_D. The viscosity of a pulp containing slime increases rapidly with increasing solid content beyond 15 per cent. although concordant experimental data are difficult to obtain. This fact explains why the much slower rising current of thick pulp in the test recorded in Table 39 lifted larger particles than the relatively rapid current of dilute pulp. Usual dilutions in mill practice are given in Table 40.

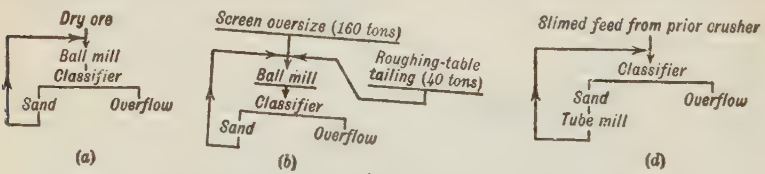

FIG. 38*a*.—Flow-sheets involving Dorr classifiers reported in Table 40.

Size of feed particle. The effect of solid particles on specific gravity and viscosity of a pulp is greater the smaller the particles. Hence the more fine material present in a pulp containing a given percentage of solids, the coarser the particles that can be overflowed. This is clearly shown by comparison of columns 10 and 11, Table 40, and the corresponding screen tests. If the feed is coarse and coarse overflow is desired, steep slope, high rake speed and low dilution are employed (columns 1 and 2, Table 40); for fine overflow, a flat slope, low rake speed and dilute pulp are usual (columns 21, 22). The low dilution in column 23 is exceptional and the effect in coarsening the overflow is apparent on comparison of screen tests 60 and 63, Table 40*a*.

Character of ore. Ores of high specific gravity must be treated in pulps of relatively high specific gravity and high viscosity in order to lift the desired particles over the tailboard. With such pulps clean separation is difficult or impossible and much material that should overflow must be sent with the sand discharge in order to prevent excessive amounts of oversize in the overflow. The performances of classifiers 11 and 12, Table 40, on heavy sulphide ores are typical of the trouble encountered.

Performances of Dorr classifiers under many varying conditions are given in Table 40.

F = Feed. S = Sand. O = Overflow.

Capacity depends primarily upon the size at which separation is to be made and upon the character of the ore. Table 41, summarized from Table 40 and from other data not sufficiently complete to be included in Table 40, gives the capacities to be expected with normal ores, specific gravity 2.6 to 2.7, and not containing an undue proportion of clayey material. Heavy ores and ores containing considerable clayey material must be run at a lower rate, if overflow is closely limited as to maximum size; clean silicious ores can be treated at higher rates.

Table 41. Capacity of Dorr classifiers

Size at which separation is made		Slope of bottom, inches per foot	Strokes per minute	Percentage of solids in overflow	Tons per 24 hr. per foot of width	
Mesh	Mm.				Sands raked	Overflow
20	0.833	3 –3.75	27–30	45–50	200–250	90–100
28	0.589	3 –3.5	27–30	40–45	150–250	60– 90
48	0.295	2.6–3	20–25	25–30	150–225	50– 80
65	0.208	2 –3	17–25	20–25	100–200	40– 60
100	0.147	1.5–2.5	10–15	15–20	50–100	20– 40
200	0.074	1.5–2	10–12	5–10	30– 75	10– 20

Power consumption ranges from about ¼ hp. for a standard simplex machine under light load to not more than 1 hp. for a heavy duplex under large load. When individual drives are provided, it is wise to install not less than 1-hp. motor for the light machine and 2-hp. for the large machine in order to take care of rushes of sand and starting.

Repairs are substantially negligible. The only wearing part is the rake. The life reported for rakes varies from 90 days, in acid water, to several years in service where corrosion is not a factor. The tank bottom is protected by a layer of sand. At some mills, *e.g.*, UTAH COPPER, the tank is made of reinforced concrete. At the PHELPS DODGE, Morenci plant, the usual steel tank is cement lined. The mechanism is designed for rake speeds as high as 30 strokes per minute and no serious wear or breakage is experienced at this and lower speeds. SHATTUCK ARIZONA, operating at 27 strokes per min. and heavy load, charges delays to these facts.

Character of products. There is a distinct relation between consistency of overflow pulp and size of particles therein, as shown in Table 40. With normal ores these figures cannot be varied greatly. If thicker pulps are wanted at a given size, some dewatering device must follow the classifier. The moisture content of the sand may be lowered somewhat beyond the figures in Table 40 by special provisions. The dewatering lip described on p. 597 is highly efficient in some cases.

Söhnlein (*96 J 215*) cites an instance where the moisture content of the sand was reduced from 60 to 12 per cent. by such a device. A porous bottom near the sand-discharge end, connected to a vacuum pump, has been used in special instances. A water spray playing on the sand just above the pulp level removes appreciable amounts of slime, if the sand bed is not too thick, and the cleaner sand will drain to a lower moisture content. Wood chips are removed from the overflow by a screen placed substantially horizontally above the overflow-discharge box. At Hollinger (*98 J 213*) a push rod with a scraper was attached to the rake mechanism to clean such a screen.

Dorr multi-deck classifier is shown in Fig. 39. The original pulp feed is introduced at (*a*) and the first deck operates in the usual manner, discharging sands into the second tank by means of the upward prolongation

of the bottom. The overflow lip of the second tank is at (b) under the prolonged bottom of the first tank. Sand is similarly re-washed in the third tank. Sprays are provided for additional washing of sands, if desired. The principal use of this device is in hydrometallurgical processes, such, for instance, as in washing leached sands in cyaniding or in leaching ores containing highly soluble copper compounds. Each machine is a special job, hence there is no limitation to standard sizes. Hardwood and gun-metal rakes have been used for resisting the chemical action of solutions. The tank is usually made of wood.

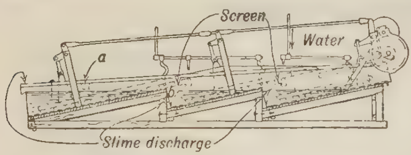

Fig. 39.—Triple-deck Dorr classifier.

Dorr bowl classifier (Fig. 40) is designed for separation at finer sizes than can be efficiently handled by the standard Dorr classifier, *viz.:* for 0.15-mm. and smaller. It consists of a shallow cylindrical pan or bowl (*a*), containing a thickener mechanism (*b*), (see Sec. 16, Art. 6), operated by belt from the classifier drive shaft, the whole mounted at the overflow end of the typical Dorr-classifier. A well, open at the bottom, extends from the floor of the bowl, at the center, into the classifier proper and terminates at a height that will clear the rakes. The sides of the classifier tank are high enough so that the level of liquid pulp in the tank can be carried above the level of the peripheral overflow lip of the bowl. Feed is introduced into a circular feed compartment at the center of the bowl. Liquid flows to the periphery and overflows, carrying the finest solid. Sands settle to the bottom and are raked to the central well by the thickener mechanism. Water, introduced through spray pipes (*d*), flows from the body of the classifier upward through the well and the solids settling from the bowl are subjected to a washing action that lifts slime back into the bowl for another chance to overflow. The sand that settles is raked up along the bottom of the classifier proper in the usual fashion. It is subjected to further working and washing by spray water which puts more slime into suspension to be carried back into the bowl.

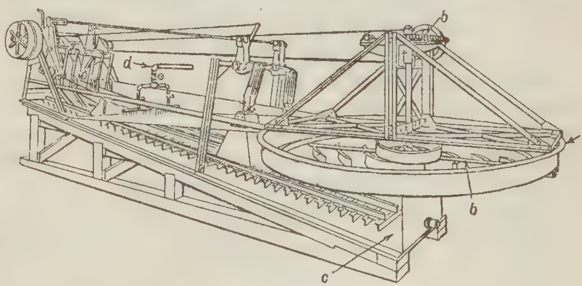

Fig. 40.—Dorr bowl classifier.

Size and speed. Bowls may be mounted on any size Dorr classifier. The diameter of the bowl depends upon the size of overflow product desired and the tonnage and dilution of the feed. Six- to 15-ft. diameter is the usual range. Rakes are operated at 12 to 25 strokes per minute, the same considerations governing as in the standard classifier. Too great speed, while tending to produce a very clean sand product, keeps a large amount of coarse material circulating between the bowl and the classifier proper and cuts down capacity proportionately. The revolving mechanism runs at 1.5 to 8 or more r.p.m. depending on the size of bowl and the amount of sand to be raked. Table 42 indicates that higher bowl speeds (in conjunction with higher rake speeds) increases capacity of the bowl and materially decreases the circulating load of finished material sent through the

grinding mill. The classifiers were 16-ft. bowls on 6 × 26⅔-ft. tanks, installed at the Springs mine, Witwatersrand; the ore makes very little slime. (*PP 1560-B A.*)

a Practically all sulphide.

Principle of operation is substantially the same as that of the standard classifier with the exception that the rising velocity in the bowl is not so much affected by the surge of pulp due to rake movement as is the overflow of the standard classifier. The speed of the bowl mechanism is not enough to cause centrifugal force to act effectively on the solid particles. The swirl of pulp aids in working sands in suspension toward the center by reason of the tendency of the solid particles to move toward the region of least velocity.

Performance. At Miami Copper Co. two machines having 13-ft. bowls mounted on 4½-ft. duplex classifiers treated flotation tailing ground to pass 48-mesh. The overflow was sent to waste and sand was concentrated on Plat-O sand tables. Sizing-assay tests of feed and products of one classifier are given in Table 43.

At Nipissing a bowl mounted on a simplex classifier treated 68 tons per 24 hr. of stamp-mill product, sending sand to a tube mill with tube-mill discharge returned to the classifier. The tube-mill circuit was 74 tons per 24 hr. The classifier overflow contained 8 per cent. solids and the sands 20 per cent. moisture. Screen tests of feed and products are given in Table 44. This classifier ran in parallel with standard 4½-ft. duplex classifiers. (See Table 40 for performance of the duplex machines.) The overflow of the primary classifier went to 4½-ft. duplex classifiers with 15-ft. bowls. The original feed to each was 120 tons per day; tube-mill return, 52.8 tons.

Treating a clay at the rate of 1.4 tons per sq. ft. of bowl area per 24 hr. in a 3-ft. bowl, with about 5 per cent. solids in the overflow, the latter contained 98.3 per cent. −330-mesh material. In this work the feed contained about 0.1 per cent. +100-mesh, sand discharge about 12 per cent. −330-mesh. Rake speed was 7 strokes per min.; revolving arms, 2.5 rev. per min.; slope, 2 in. per ft.

At the plant of the Benjamin Moore Co. (*116 J 418*) a 10-ft. bowl on a 2-ft. 3-in. × 18-ft. simplex classifier treats ground chalk rock. The rakes are run at 8 strokes per min., bowl rakes at 1.5 r.p.m., overflow contains 5.5 per cent. solids. Sizing tests of the products are given in Table 45. At St. Joseph Lead Co., Bonne Terre plant, a 6-ft. duplex classifier with 12-ft. bowl was used to dewater 2200 tons per 24 hr. of combined jig and table tailing. A sizing test of the dewatered product is given in Table 46. The rakes were run at about 30 strokes per min.; bottom slope, 2¼ in. per ft. The feed contained 65 per cent. water; the sand, 16 per cent.; the overflow, 98.5 per cent. Table 47, from the Dorr Co. catalog, shows results with several different bowl diameters treating a roasted ore. The capacities are probably considerably higher than on unroasted ore. At the Mesabi Iron Co. (see p. 148) a 9-ft. bowl in closed circuit with an 8-ft. × 22-in. conical ball mill overflows 8.6 tons per hr.; the sand circuit is 52.6 tons per hr.; sizing tests are shown in Table 48.

Capacity and dilution. Capacity is dependent principally on the area of the bowl and the separating size.

Miami overflows 3.6 tons per sq. ft. per 24 hr. at 65-mesh separation; Golden Cycle, from 3 to 8 tons at 100-mesh and 2.2 to 7 tons at 150-mesh separation; at Nipissing about 1 ton per sq. ft. is overflowed with 200-mesh separation. The test on clay showing 1.5 tons per sq. ft. at 330-mesh separation was made on a feed containing relatively little coarse material so that the sand could be handled with low rake speed.

Table 48. Sizing tests of feed and products of bowl classifier at Mesabi Iron Company

Mesh	Feed, per cent. weight	Sand, per cent. weight	Overflow, per cent. weight
+14	60.01	11.41	....
+48	21.84	21.77	....
+100	4.85	29.41	4.66
+150	1.89	16.32	5.25
+200	0.44	9.82	7.37
+350	3.38	6.83	32.23
−350	7.59	4.44	50.49

Dilution for 65- to 100-mesh overflow should be 20 to 25 per cent. solids, for 200-mesh about 10 per cent. and for 300-mesh 5 to 6 per cent.

Use of chemical agents. (See also Sec. 16, Art. 4.) The settling rate of fine particles is markedly affected by certain chemical agents, some of which cause flocculation, others dispersion. When separation is to be made at 200-mesh or finer the effect of these reagents on the products is great. Flocculation increases the settling rate of the fine particles and coarse particles become entangled in the flocs, hence overflow will be finer and more fine material will be carried into the sand. Dispersion, on the other hand, increases the amount of slime that is carried over in the water going with the sand discharge, and may result in a coarser overflow than with flocculated pulp. In every case the result is a matter of experiment. It must be realized, however, that the chemicals necessarily present in cyanide treatment will affect settling and that preliminary grinding and settling-tests must, therefore, be made in solutions approximating those to be met in the operating mill.

Akins classifier (Fig. 41) consists essentially of a spiral ribbon revolving in a semi-cylindrical inclined tank closed at the lower end. The spiral is single and continuous from discharge end to the point at which the ribbon does not enter the settling pond; above this the spiral is double and interrupted. The principle of operation is the same as that of the Dorr classifier. For very fine separation, *i.e.*, at 150- or 200-mesh a larger settling pond is obtained in a submerged type of machine in which the tank is flared at the overflow end and the overflow lip raised so that the lower bearing must be carried in a stuffing box. For coarse overflow, increased agitation is affected by lessening the pitch of the standard spiral toward the overflow end and joining adjacent parts of the spiral ribbon by straps which serve to stir up the material settled in the pond and cause fine sand to overflow.

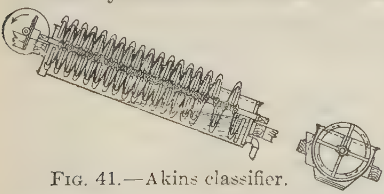

Fig. 41.—Akins classifier.

Performances, as given by the manufacturers, are shown in Table 49. Ten 54-in. machines were used at United Comstock to de-slime 2000 tons per 24 hr. of − ½-in. primary feed. (*114 J 850.*) At U. S. S. R. & M. Co., Midvale plant, a 30-in. machine was used to dewater 45 tons per 24 hr. of sands passing a 0.020-in. screen and containing no slime. Bottom slope was 2¼ in. per ft.; the spiral revolved 13 times per min. Feed contained 72 per cent. water; sand, 19 per cent.; the overflow was substantially clear water. Life of spiral, 518 days. At the Royal Asturiana Mining Co. plant (*115 J 396*) a 24-in. machine treating − 2-mm. feed (sp. gr. of solid 3.0 to 3.5) had to be run at 30 r.p.m. on a

a Submerged type.

slope of 3 in. per ft. in order to obtain −48-mesh overflow when making 65 tons overflow per 24 hr. and under such conditions the sand contained 30 per cent. of undersize (−55-mesh). Sizing tests of feed and overflow are given in Table 50.

Effect of solutes on performance. Stowell (*117 J 362*) reports that the addition of 1 lb. sodium sulphide per ton of solid to the feed of an Akins classifier made it substantially impossible to overflow sand, with the result that, if the spiral was run at the speed for normal operation, sand built up in the settling basin until unclassified sand overflowed. Table 51 shows the effect on a 30-in. machine sloped 2 in. per ft. and making 12 r.p.m. when running in closed circuit with a 5 × 4-ft. ball mill.

Drag classifier (Fig. 42), sometimes called ESPERANZA CLASSIFIER, consists essentially of an endless band (*a*), which carries flights (*f*) and runs on wheels (*b*) and (*c*), all mounted as shown in a trough (*d*) with inclined bottom. The band (*a*) may consist of link chain or rubber belt. Feed enters the trough at the lower end, water carrying fine solids in suspension overflows the sides of the trough, sand settles to the bottom, is dragged up-slope by the flights, and discharged at the upper end. The principle of operation is the same as that

of the Dorr classifier and the adjustments to effect variation in character of products are similar.

Performances at several mills are given in Table 52.

In another type of drag classifier the sand settles on the drag belt and is carried by it above the pulp surface; slime overflows in the usual fashion. The disturbance is less than in the ordinary type and finer sand is, therefore, collected. At INSPIRATION two 18-in. belts are set side by side in one tank; the distance center to center of head pulleys is 39 ft.; the vertical distance from the overflow lip to the lower run of the belt is 5 ft. The machines are used to separate sand, for tabling, from flotation tailing (see Sec. 2, Fig. 61).

Dorr hydro-separator is a Dorr thickener of relatively small diameter fed at such a rate that slime instead of clear liquor overflows. It is used in the anthracite fields to separate −200-mesh slime from breaker slush, the spigot product being dewatered and used for mine fuel while the overflow is sent to a Dorr thickener and dewatered. Performance at one plant is shown in Sec. 16, Table 1.

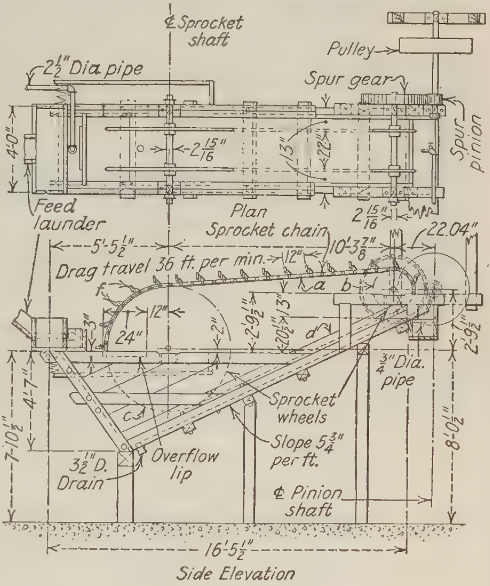

FIG. 42.—Drag classifier.

7. Comparison of classifiers

For separating sands into several grades hydraulic classifiers are far superior to all other types, principally on account of the fact that slimes are substantially excluded from the spigot products. Their great disadvantages are the large water consumption and the excessive dilution of the slime overflow. Hindered-settling classifiers yield spigot products better adapted to table concentration than those of free-settling classifiers, on account of the greater ratio of diameters of light- to heavy-mineral grains in the spigot products, but this ratio in most cases is far below the theoretical figures and below experimental results. The Richards-Janney is the most successful of the hindered-settling machines. Its principal advantages are steadiness of operation due to prevention of banking by the stirring mechanism, low water consumption by reason of the intermittent spigot discharge, and low moisture content of spigot product, which permits close control of the moisture content of the feed to the tables following. Launder-type machines have two great advantages over the tank type, *viz.:* (1) that the spacing of the sorting columns

may be adapted to the location of the concentrators following, thus eliminating a maze of launders radiating from a group of closely-spaced spigots; and (2) saving in head room. It is more difficult, however, to keep slime out of the spigot product of the launder classifier and, if slime is present in the feed, more coarse sand is carried into the later spigots. It is fairly well agreed that de-sliming the feed to any type of hydraulic classifier improves the performance of the machine and also separates a much less dilute slime.

For sand-slime separation and for dewatering sands, mechanical classifiers are most widely used, but diaphragm cones, particularly of the automatic type, are strong competitors. When the service required is to de-slime grinding-mill discharge and return sand to the mill, mechanical classifiers have unquestioned advantage because of the fact that they do their own elevating of the sand in the course of the separation, while cones require separate elevators. Cones require no power for their operation, but cause considerable loss of head room for the sand product, and the power required for re-elevation, when necessary, must be charged to the cone. This power will usually exceed that necessary to operate a mechanical classifier. Further, the gritty character of the material to be elevated causes excessive wear on all kinds of elevating apparatus.

Bates (*73 A 239*) gives a comparison of Caldecott cones, Dorr duplex classifiers and Dorr bowl classifiers at the GEDULD mill, Witwatersrand. The classifiers were working in closed circuit with tube mills, but the tests were not strictly parallel; reduced to terms of performances with a 5½ × 22-ft. tube mill, the results were as follows:

Classifier	Tons produced by tube mills per 24 hr.	
	−90-mesh	−200-mesh
Cones	140.0	109.5
Dorr classifier	160.3	127.1
Bowl classifier	163.4	137.9

On the basis of separating efficiencies alone, cones are generally superior to mechanical classifiers; they give a sand product containing less undersize and, in general less tramp oversize in the slime. They are also extremely efficient in dewatering. Comparative efficiencies are given in Table 53.

Comparison of mechanical classifiers. On the basis of the figures in Table 53, it would appear that the Akins yields the cleanest sands and that the overflow of the Dorr contains the least oversize. The chain-drag is the poorest on both counts. The efficiency of the Akins is best, so far as the tests given in the table go, but the number of performances included is small and these are presumably the best. Table 54, published by J. V. N. Dorr (*14 CME 296*) in answer to a generalization similar to that above made, seems to show that under strictly competitive conditions the superiority of the Akins sand is obtained at serious sacrifice of the character of overflow and that when the tonnage to the Akins is reduced to the point where overflows are of the same general character in both Akins and Dorr machines, the sand products are likewise similar and the capacity of the Akins much less than that of the Dorr.

Power consumption is so small for all types as to be an unimportant factor in the comparison; it is greatest in the chain-drags. Wear is greatest in the drags and least in the Dorr but is not excessive in any of the three. Bearings are furthest from the pulp in the Dorr, which is a point of considerable impor-

a −200-mesh.

tance. The drag type has the distinct advantage for small or temporary plants that it can be built locally and will probably cost less installed than either of the others. Local construction also permits considerable latitude in area of settling pond and length of draining space. In de-sliming service, the drag type is usually reported as less efficient than either of the other types.

The bowl-type is superior to all of the others for separation at 100-mesh or finer.

SECTION 7

HAND SORTING

1. Introduction

Hand sorting or HAND PICKING is manual removal of selected grades of material from a mass of broken ore. A concentrate of high-grade or SHIPPING ORE is one of the grades commonly selected. Such material may be worth more per ton, on account of its size, than mill concentrate, and, if taken thus early, is not subject to the danger of loss attendant on further treatment. Tailing or WASTE for rejection is likewise frequently made. The advantage of this practice is increased capacity from a given mill equipment, increase in the possible mining rate, and reduction in wear on mill equipment. Even if increased capacity is not utilized, there may be marked increase in efficiency because of the reduction in load on the mill. Sometimes both shipping ore and waste are picked at the same operation and a third class, *viz.:* MILLING ORE, requiring mechanical treatment, is the residue. High-grade complex ores may be picked into several classes; as many as sixteen have been made at one time at CLAUSTHAL (*4 SMQ 196*). Such close work requires breaking with hammers in addition to the actual sorting. Breaking with heavy long-handled hammers is called SLEDGING; further breaking of sledged material with light long-handled hammers is called SPALLING and final breaking with light short-handled chisel-peen hammers is called COBBING.

Sledging, spalling and cobbing are rarely practiced in the United States except around prospects and one-man mines, but they are established practice in many foreign countries. At certain CORNWALL mines picking and cobbing produce (*a*) rich copper pyrite, (*b*) coarse, rich galena, and (*c*) coarse rich blende, all of which are sent directly to the smelters; (*d*) fine tin oxide, (*e*) pyritiferous milling ore, (*f*) waste. At CLAUSTHAL (1880–4) six products were made from the original ore, *viz.:* (*a*) copper pyrite, nearly pure, (*b*) mixed copper-iron pyrite with copper predominating, (*c*) the same with iron predominating, (*d*) iron pyrite, nearly pure, (*e*) pyritiferous milling rock, (*f*) pyrite-chalcopyrite-galena-blende-gangue middling. The first four were sold to smelters, the fifth milled and the sixth further cobbed by expert workmen, producing: (*g*) galena, (*h*) mixed copper and iron pyrite (distributed between (*b*) and (*c*)), (*i*) intergrown pyrite and galena, (*j*) galena milling rock, (*k*) pyritiferous milling rock, (*l*) mixed pyrite and blende. Lots (*i*), (*j*) and (*k*) were accumulated and milled separately; (*l*) was further cobbed. These are extreme cases, but they result in salable products from an ore from which such products can be made only with extreme difficulty, if at all, by the most refined of modern concentrating methods.

When the ore-treatment process is chemical, sorting may be resorted to to remove deleterious substances, such as those that consume chemicals, hinder settling and filtration, absorb and carry valuable solutes into tailing, etc.

Apart from the necessity for removing refuse such as rope, wood, steel, dynamite, etc., from any mill feed and dangerously deleterious substances from feed to chemical ore-treatment processes, the decision as to the advisability and extent of sorting is purely economic. The cheaper the labor and the more inefficient and expensive the mechanical treatment, the further sorting can be carried and *vice versa*. Undoubtedly sorting could be introduced with

advantage in many plants, but just as undoubtedly it is being practiced in some places where economy demands its discard or curtailment. For investigation of the economics of sorting, see Sec. 22, Art. 19.

Sorting of some kind is a part of every mining and ore-treatment operation. In narrow ore bodies with distinct walls, much of the country rock that is unavoidably broken in mining is sorted out underground and left or used for filling. In certain mines in which the ore contains segregated masses of pure valuable mineral, as in some of the Lake Superior native-copper deposits, the valuable mineral is picked out underground and sent to the surface separately. In general, however, underground sorting is uneconomical on account of restricted working places, poor lighting, poor presentation of material and the obscuring effect of the fine dirt present. Some sorting to remove wood, rope ends, powder and tramp steel is done ahead of the primary crusher in practically all mills. This work is, however, incidental to crusher operation and is hardly to be considered as a part of the general problem.

When valuable mineral occurs in ore as coarse aggregates, or when considerable waste is mined with the ore and the mineral and gangue or ore and waste are readily distinguishable by eye, the economics of sorting should always be investigated.

2. Sorting surfaces

Sorting is performed on floors, stationary tables and grizzlies and on various sorts of moving surfaces such as revolving tables, conveyors of the pan or belt variety (see Sec. 20) and shaking surfaces such as shaking feeders or shaking screens or grizzlies. In modern practice in United States and on the Rand the material fed to sorting surfaces is prepared mechanically and there is little or no breaking during sorting, but in European and some Latin American mills considerable breaking (spalling and cobbing) of the ore is done during sorting.

Floors are used for sorting where labor is cheap or where spalling and cobbing are practiced. In its crudest form a sorting floor is any level space with a surface that can be swept up thoroughly, on which the ore to be sorted is dumped and picked over. The usual practice in such sorting yards is to let the work on contract, assigning to each contractor a certain space on the floor, delivery of feed and collection of products being made by the company. With coarsely-aggregated complex sulphide ores, such as the German and Austrian lead-zinc-iron ores, Cornish tin ores and certain Bolivian tin ores, it is possible by such methods to get out high-grade salable concentrates that could not be separated, or could be separated only at great expense, after grinding. The costs of such work are so variable and so dependent on the ore, the products required and on local custom as to be entirely unreliable for quotation. Sorting floors have been carried to their highest development at some of the Rand gold mines.

Fig. 1 shows one arrangement. The floor was covered with ½-in. steel plate.

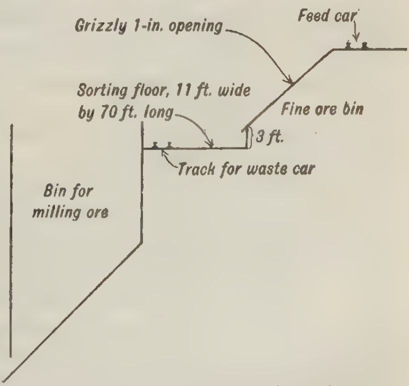

FIG. 1.—Arrangement of sorting floor at a South African cyanide plant.

About 550 tons per 24 hr. was fed over the grizzlies by two men per shift. Nine men per shift on the floor dragged the oversize out with heavy 2-pronged rakes, washed it, did some sledging, sorted out about 70 tons of waste per shift, and threw this into cars on the floor, while coarse milling ore was shoveled over into the coarse ore bin at a cost (1896) of about 35¢ per ton sorted. Waste was quartzite and some slate, the ore a cemented conglomerate.

The DISADVANTAGES of floors are that all material must be moved manually and that the sorters must work in a stooping position, which is tiring. The ADVANTAGE is thorough inspection, since every piece of material must be turned over and the pickers are not unduly hurried.

Table for sorting is shown in Fig. 2. Feed is delivered by cars or wheel barrows running on the floor at the left and is dumped onto a perforated plate submerged 1 or 2 in. in water in tank A. Shovelers standing on this plate work fines through the screen and wash the coarse oversize, then shovel it onto the inclined table B. Pickers sitting on plank C remove whichever separable component of the feed is present in smallest bulk and drop it below them into proper receptacles, finally scraping the residue through the opening into the tank below B.

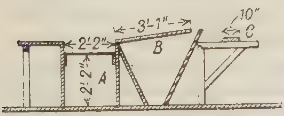

FIG. 2.—Hand-sorting table (*after Richards*).

For sorting on a small scale a punched-plate screen set horizontally on horses or the like is recommended as superior to a floor or table (*106 J 412*). It saves stooping, screens out, during the sorting operation, material too small to pick, and the reject is readily hoed off at one end.

Fixed chutes and grizzlies for sorting are of the usual types with the limitations, however, that their slope shall be near the sliding angle of the material (see Sec. 20, Art. 9) and that the width shall not exceed that readily inspected and worked, viz.: about 24 to 30 in. when worked from one side and 48 in. when worked from both sides. If the slope is less than the sliding angle, material is worked along with rake or hoe; if more, the flow is stopped as desired by a board, hoe or shovel inserted into the stream. Such sorting surfaces are not used when a large percentage of the total material is to be removed or when close sorting is desired. They serve principally when rope, wood, powder and steel are being taken out of the primary-crusher feed in order to obviate trouble in the mill. A grizzly makes selection easier than a chute because of removal of fines, but if the particles are tabular or wedge-shaped, the grizzly clogs badly at the low speeds at which material passes and it is, consequently, difficult to control the movement of material.

A sorting grizzly of adjustable slope used at the PORT HENRY IRON ORE CO. at Mineville, N. Y., is shown in Fig. 14, Sec. 5.

Moving surfaces for sorting include belt and pan conveyors, revolving tables and shaking chutes and screens. Such surfaces have the advantage that manual handling of rejected material is eliminated, but this rejected material is not turned over by or for the picker and material is therefore passed by oversight that should be removed. Further, all material passes at a given uniform rate, irrespective of the content of material that should be removed, with the result that pickers are, at certain times, hurried beyond their capacity and at other times are underworked, if the average speed of travel is right. Notwithstanding these drawbacks, most hand sorting at present is done on movable surfaces because of the advantage of mechanical transport of the reject.

Belt conveyors (see Sec. 20, Art. 1) are the most usual picking surfaces. Belts are commonly 24 to 30 in. wide for a single row of pickers and 48 in. wide

for a double row. Stations for operators are placed 3 to 6 ft. apart along the belt and chutes are provided at each station for receiving the material removed. These chutes are placed beside the picker or on the opposite side of the belt. It is probable that chutes on the opposite side are best for material up to 3- or 4-in. that can be thrown by a flick of the wrist, but pieces that need two hands are best drawn toward the picker and it is probably less tiring to draw one-hand pieces larger than 4-in. to the picker's side than to throw them away. Chute mouths should be so large that accurate throwing is not necessary and of such conformation that pieces will not tend to bound out. Speed of belts ranges between 10 and 80 ft. per min.; the average speed is between 30 and 40 ft. per min. The more difficult the job., *i.e.*, the smaller the pieces and the greater the amount to be removed the slower the speed and the longer the belt.

Tuttle (*17 SMQ 396*) states that coal-picking belts are usually 4 ft. wide and run at 30 to 60 ft. per min. For picking oversize of a 1.5-in. screen at 30 tons feed per hour he recommends a belt length of 15 ft. plus 10 ft. for each 3 per cent. of material removed. On 0.75- to 1.5-in. sizes he recommends 30 ft. per min. belt travel and, for a feed rate of 20 tons per hour, 15 ft. of belt for every 1.5 per cent. of material removed. For more than 4 to 6 per cent. of impurity he recommends washing rather than picking.

The belt should be troughed as little as possible to prevent heaping-up in the middle. In many cases a wide flat belt with feed coming on not nearer than 6 in. from the edges is used. A belt conveyor is suitable as a sorting surface for any size of material that can be handled by the pickers, but it will not stand any considerable amount of sledging, and wears excessively with feed coarser than 6- to 8-in. particularly when, as should be the case, the fine material has been screened out. It may be set on a slope not to exceed 20°.

Pan conveyor (see Sec. 20, Art. 2) is used for coarse material. The arrangement is similar to that described for belts. The speed is usually slower, both for mechanical reasons and because larger lumps are handled. A pan conveyor will stand sledging and is less subject than belts to wear from large lumps. The best form for sorting is one forming the bottom of a shallow trough, which has, therefore, stationary sides. This permits removal of large heavy lumps more readily than when articulated sides form part of the moving mechanism. At Shuler Coal Co. (*21 CA 1077*), a picking pan conveyor 72 in. wide is run at 50 ft. per min. and spreads run-of-mine bituminous coal about 8 in. deep.

Pan conveyors, if beaded or the equivalent may be set on slopes up to 30°, although material will pile up somewhat against the beads and not be so well presented as on flatter slopes.

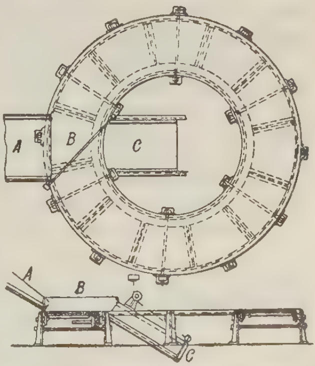

Fig. 3.—Revolving picking table.

Revolving table. One form is shown in Fig. 3. A metal picking surface (usually inclined toward one edge) is carried on a structural frame with a circular track running on suitably placed wheels on the supporting frame. The platform is revolved by means of gear and pinion. Feed is introduced through chute (A), pickers stand or sit at suitably placed stations around the outer and inner peripheries and throw material removed into appropriate chutes or other receptacles. Reject is removed by a scraper (B) and falls into chute (C). Some

tables are supported by ribs from a central spindle, which prevents picking stations on the inner periphery. The usual outside diameter ranges from 16 to 25 ft.; speed is usually between 20 and 40 ft. per min. Some tables are double-decked. The upper deck is about half the width of the lower and 6 in. higher; it receives the selected material, thus presenting both reject and selected material to the inspector.

Revolving tables have been largely used in So. Africa and in Europe, but installations in the United States are rare. German tables are 12 to 15 ft. diam. and 12 to 16 pickers work at each table The cost of sorting on revolving tables on the Rand, where the feed is washed oversize of 1.5- or 2-in. screen, averaging 3-in. size, is 18 to 50¢ per ton, pre-war. (Truscott, *Witwatersrand gold fields*, p. 413.)

The ADVANTAGES are compactness with consequent ease of supervision and collection of products; DISADVANTAGE, as compared to rectilinear conveyors, is the loss of elevation suffered by the reject.

Shaking surfaces have been used widely in collieries, but, except as primary-crusher feeders have not been used to any extent in metal-treatment plants. They are essentially chutes with perforate or imperforate bottoms, set on an incline of about 10° in the direction of flow and shaken at 100 to 250 @ 2- to 6-in. throws per min. by a simple eccentric. With the Ferraris method of suspension by means of short struts or hangers inclined backward about 15° from the vertical, or with a differential head motion (*e.g.*, Marcus screen) the picking surface may be horizontal. Limitations of width and the arrangement of receptacles are the same as previously discussed.

These are the least satisfactory of the movable picking surfaces for careful picking, but when screen bottoms are used, they serve the triple purpose of screens, conveyors and sorting surfaces and thus justify themselves.

3. Operation

Material picked should be that present in least amount in the feed, thus leaving the larger bulk unhandled. Wiard (*112 J 328*) recommends removing ore (one or two classes as the case may be) whenever the tonnages of ore and waste are approximately equal. His argument is that this puts a single and easily defined responsibility on the picker, *viz.:* to remove everything that looks like ore, and makes inspection of the products more simple.

Washing of feed is essential to rapid and accurate sorting. It is usually done in the trommels removing oversize, but may be done by hose or sprays on floors or moving sorting surfaces. Spray water run on to a troughed inclined belt just above the feed point will wash fines down the incline and over the tail pulley where they can be collected in a suitable receptacle. For the quantity of wash water required in trommel washing of non-clayey ores see Sec. 5, Art. 5; for clayey ores see Sec. 8, Art. 1.

Performance at various mills is given in Table 1.

At BRITANNIA M. AND S. Co. (*113 P 695*) the ore is cupriferous pyrite in chloritic schist assaying about 2.7 per cent. Cu, 8 per cent. Fe, 1.5 per cent. Zn, 6 per cent. S, 70 per cent. SiO_2, 25¢ Ag and a trace of gold. Material ranging from 1.5- to 3.5-in. is picked on a belt. Four men per shift at two belts pick shipping ore and hard pieces of country rock for tube-mill pebbles from the oversize from 600 tons per 24 hr. Shipping ore comprises about 10 per cent. of the total concentrate and assays 10 to 18 per cent. Cu. The concentrate shipped assays 15 to 16 per cent. Cu and is composed of the foregoing together with jig concentrate, 16 to 17 per cent. Cu; table concentrate, 14 to 15 per cent. and flotation concentrate, 14 to 15 per cent.

HANDY (*61 A 224*) states that the labor in a typical COEUR D'ALENE sorting plant, in which 800 tons per day, sorted at 1.5- to 4-in. size, yielded 50 tons shipping ore and 150 tons waste, consisted of 20 sorters with 5 bosses and repair men. The normal cost (1917)

was 16¢ per ton of run-of-mine rock or 65¢ per ton sorted out. Picking coal on belts in English fields, with the percentage removed ranging from 2.1 to 17.5, the tons picked per worker per hour varied from 0.03 to 0.35, with the highest tonnage corresponding to the greatest percentage removed and general, though not exact, adherence to this rule.

(*Louis, p. 98.*) Huntoon (*93 J 53*) gives the COST of sorting 15 to 20 per cent. of waste from belts at TONOPAH BELMONT at $0.68 per ton of waste and at TONOPAH MINING CO., $0.80 per ton removed when this comprises 11 per cent. of the feed.

Amount removed by sorting varies according to the ore treated.

With native-copper ores of Lake Superior the amount is as small as 0.001 per cent. of the whole at COPPER RANGE. At FEDERAL MINING AND SMELTING CO. lead mines and at WITHERBEE SHERMAN magnetite mines 20 per cent. total high-grade ore and waste are removed. At ALASKA JUNEAU (*112 P 632*) 7.73 per cent. of the total mill feed was picked as milling ore assaying $5.06 per ton and 34.64 per cent., the balance of the 2-in. trommel oversize, rejected as 7-cent waste. On the RAND (*20 IMM 307*) material from 8-in. to 1.75-in. constitutes 50 to 70 per cent. of all rock hoisted. Waste picked out of this varies from 10 to 30 per cent. of the total hoisted, averaging about 16 per cent. This constitutes about 50 per cent. of the total waste hoisted. In IDAHO mills treating coarsely-disseminated lead ores, shipping ore picked out varies up to 60 per cent. of the total concentrate produced.

Labor is generally that unfit for any heavier work, boys, girls, women, or old or crippled men. Boys and girls are the quicker and, if properly supervised, most satisfactory.

Size of material sorted ranges on the average from 2.5- to 12-in.

Smelting ore as fine as 0.75-in. is picked at the Morenci plant of PHELPS DODGE and as coarse as 24-in. at the Ogdensburg plant of N. J. ZINC CO., but the number of moves necessary to make tonnage on the small sizes is so great that the capacity of pickers is low, and difficulty in deciding about and handling 24-in. lumps is likely also to slow the operation down below the rate on intermediate sizes. Wiard states (*112 P 327*) that the best size range for sorting is between 1- and 3-in. Richards (*TB 196*) estimates the maximum rate to be on 3- to 4-in. lumps, but Table 1 shows that maximum tonnages per man-hour correspond to feed averaging 6- to 12-in. Comparison between FEDERAL M. AND S. CO. and WITHERBEE SHERMAN (Table 1) is particularly instructive since at both mines 20 per cent. of the feed was picked as shipping ore and waste and the number of pickers indicates sorting to have been the sole responsibility of the workers. At WITHERBEE SHERMAN 5 tons per man-hour of 4- to 16-in. material was picked against 0.34 ton per man-hour of 1- to 6-in. material at the Federal plant.

Lighting. Daylight is best but ordinarily picking must go on on all shifts, hence artificial light must be used part of the time. Since luster and color are the principal guides in sorting, the light should be good and as uniform as possible. Light should be placed, if possible, to keep shadows off the material being picked. Ordinarily diffused or flood lighting is best, but incandescent lights placed directly over the feed stream and shaded from pickers' eyes may be best in some cases. Experiment is the best guide. Ore moist from recent washing is probably in the best condition for quick and ready selection.

Cost of hand picking bituminous coal at different sizes was thoroughly investigated by U. S. Coal and Coke Co. (*Am. I. & S. Inst., 1921*). With labor at $0.55 per hr., the costs per ton, including interest and depreciation on the investment in sizing and picking machinery, for picking at various sizes were as shown in Table 2. See also Performance, above.

SECTION 8

WASHING

Introduction

Washers are of three classes, *viz.:* screening washers, classifying washers, streaming washers. Some of the members of each class are designed or arranged to effect disintegration of materials such as clays, soft shales and sandstones, as a preliminary to concentration, but this is an entirely extraneous function in so far as the separating principle is concerned. The usual methods of effecting disintegration are by high-pressure water jets, by tumbling, or by mechanical beating or stirring.

SCREENING WASHERS

Screening washers depend, for their effect, on the fact that the value of the fine and coarse particles of the material to be treated differs. Usually, as with wash iron ores, phosphate ore, bauxite ore and the like, the coarse material is the valuable constituent, but the reverse condition obtains with certain metallic ores, *e.g.*, Cripple Creek tellurides. Screening washers are used principally with ores of the first class.

1. Wash trommels

Trommel screen for washing do not differ from wet trommels in ordinary screening service (Sec. 5, Art. 5) except that when disintegration is necessary the machine is set on a flatter slope and powerful water jets play on the material in the interior. For such work screens supported on tires and rollers are better than those with a central shaft. Roller screens permit heavier construction, which is desirable when lump ore is being treated. The use of trommel screens for washing is usual in ore-sorting plants and on gold dredges.

Trommels on dredges may be 8- to 10-ft. diameter and 40 to 60 ft. long and are very heavy.

New Century wash trommel (Fig. 1) is designed especially for washing. The disintegrating surface is a cylindrical grid of heavy longitudinal bars (*a*) carried on two heavy spiders (*b*) on a central shaft. Screen cloth is stretched outside the grids and lifting buckets (*c*) are disposed on the outside of the screen. The whole is set in a shallow tank. A plow-shaped casting (*d*) fastened to the inside of the conical discharge-end lifts and discharges washed oversize. The heavier undersize is lifted from the tank by the buckets and thrown onto an apron (*e*). Suspended fines overflow the same apron.

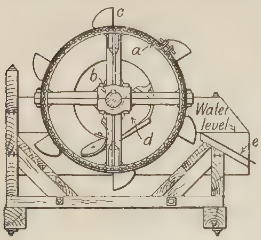

Fig. 1.—New Century wash trommel.

The diameter is 40 in., lengths from 4 to 8 ft. The manufacturer claims CAPACITIES of 75 to 300 tons per 24 hr. with consumption of 4 to 6 hp.

Grizzly and nozzle stream were used to disintegrate and concentrate in a simple and compactly arranged plant shown in Fig. 2 (*21 IMM 230*). The ore was delivered on an upper track, dumped into a chute (*A*) and brought to a washing platform (*B*) where it was disintegrated by means of a stream from a

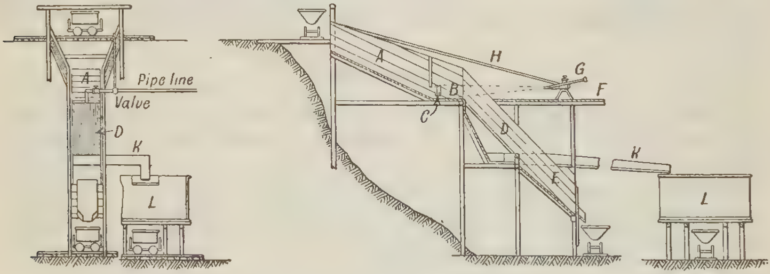

Fig. 2.—Monitor washing plant.

nozzle (*G*). Disintegrated material flowed over a grizzly (*D*), washed oversize was collected in a bin (*E*) and undersize flowed through launder (*K*) to a settling tank (*L*).

Nozzles delivering water under high pressure (50 lb. per sq. in. and upward), as above, are extremely effective in disintegrating loam, mud and light clays. They are used on sorting floors and on screens and grizzlies in sorting plants, in revolving screens on gold dredges and in gravel-washing plants, and in breaking down gravel banks in hydraulic mining. When disintegration is an important feature, the nozzle should be designed to deliver as nearly as possible a solid column of water at maximum velocity. When removal of thin, slightly-adherent layers of dirt is sought, as in preparing ores for hand sorting, delivery of the water in a thin sheet or a multiplicity of fine jets is desirable.

Dorr ore washer consists essentially of a standard Dorr classifier (Sec. 6, Art 6) and a trommel mounted above the settling pond in such a way that the lower part of the trommel is submerged. The discharge end of the trommel is fitted with a discharge scoop similar to that in a scoop-discharge tube mill.

In an exhaustive test at the Minnesota School of Mines (*Bul. 6, MSM*), the washer recovery on Lake Superior wash iron ores averaged above 90 per cent. against about 88 per cent. for a log washer and the concentrate was higher grade. Davis estimates the first cost of a Dorr plant less than that of a log-washer plant and the operating cost no higher.

CLASSIFYING WASHERS

These machines are essentially hydraulic or mechanical classifiers (Sec. 6) used as finishing machines because of the special amenability of certain ores to such one-step concentration.

2. Drum washers

Washing drum consists of an imperforate cylinder, 4- to 8-ft. diameter and 10 to 20 ft. long, set with the axis horizontal and driven at 250 to 300 ft. per min. peripheral speed. The ends are partially closed by an annular rim so that a certain amount of liquid pulp is maintained in the interior. Spirally-disposed lifting blades or ribbons are placed on the inner wall to tumble and move lumps from feed to discharge end. High-pressure water jets are set to play on the tumbling material. At the discharge end heavy solid particles are lifted by perforated buckets and discharged through a chute while water lifts the fines over the closing ring at the feed end.

Speed depends on the diameter of the drum and the character of the material treated; the higher the speed the greater the rate of progress and consequently the less the washing up to the point where centrifugal force causes material to cling to the walls. Power consumption, within the size range given, will vary between 5 and 10 hp. Water consumption is 1 to 4 tons per ton of feed. Capacity depends on the character of the feed: for fairly heavy, granular ores large machines with a long-pitch spiral run at maximum speed will wash 25 to 30 tons per hour; clayey material in a machine of the same size requires low pitch and speed and the capacity will not exceed 25 to 50 per cent. of the above.

Crickboom washer is designed for treatment of materials that are too tenacious for disintegration in the ordinary washing drum. In addition to the ordinary washing drum it has a horizontal shaft carrying beater arms which is independently driven at about 200 r.p.m. in the opposite direction to the drum moving at 10 to 15 r.p.m. The beater arms, therefore, strike and aid in disintegrating the rising material. The lifters on the drum are spaced about 0.75 in. from the shell, thus failing to lift fine material and water.

Richards (*TB 190*) gives the capacity of a 4 × 8-ft. machine as 5 to 5.5 tons of tough clayey ore per hour with a water consumption of 1.6 to 1.8 tons per ton of ore.

3. Puddling

Puddling is a method of washing in which material in a shallow cylindrical tank is stirred relatively slowly by means of sweep arms depending from an overhead sweep. In the form used in the Kimberley diamond fields feed is introduced at the periphery with only sufficient water to form a thick pulp. Sweeps revolve about 10 r.p.m. and the paddle arms are set at an angle that forces settled solid toward the outer rim while water containing suspended solids overflows the inner rim.

Operation is intermittent. When the operator judges that sufficient solid has collected in the bottom, feed is shut off, clear water is run through for a time, then settled material is swept through a bottom gate by means of a plow attached to the sweep.

Successful operation of a machine of this type depends on easy disintegration, a high percentage of clayey material and finely divided waste sand that is readily kept in suspension in the thick pulp.

4. Log washer

Description. The log washer (Fig. 3) consists essentially of a heavy log (a) carrying strong metal blades arranged spirally on its surface, the log being mounted on a slope of ¾ in. to 1½ in. per ft. in an inclined-bottom trough closed at the lower end and open at the upper. The log is so driven that the action of the blades transports material up the incline. The length and slope of the trough are such that the upper third to half of the length of the log is not submerged. The bottom of the trough is usually made to conform to the cylindrical surface generated by the blade tips with clearance between the tips and the bottom somewhat greater than the diameter of the largest lump of ore in the feed. Logs are built one or two to a trough. The usual length is between 20 and 30 ft. and the diameter, tip to tip of blades, between 24 and 30 in. Speed is from 12 to 24 r.p.m. Double logs revolve in opposite directions with the blades rising between them. Logs are made of wood or iron. Wooden logs are generally 12- to 18-in. sticks, and square, hexagonal or octagonal in section. They are shod full length with iron straps. Heavy cast-iron gudgeons (Fig. 4) are fitted to the ends, the lower gudgeon passing through a stuffing box and carried in a thrust bearing, the upper carrying the driving gear. The blades are usually chilled castings with a base for bolting to the log. Blades are sometimes made renewable in the bases, in which case the blade is special iron or steel and the base an ordinary casting.

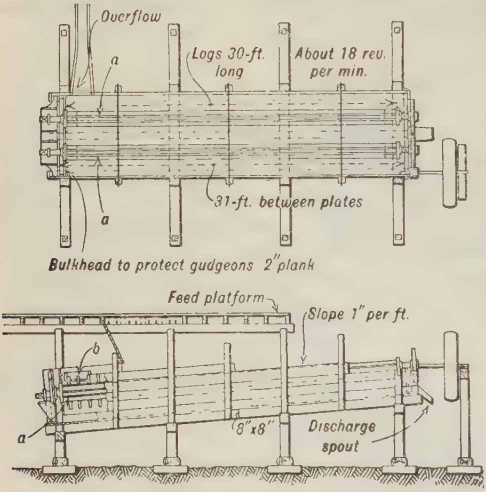

Fig. 3.—Two-log washer.

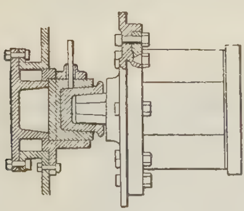

Fig. 4.—Gudgeon, chilled-iron thimble and step bearing for wooden log.

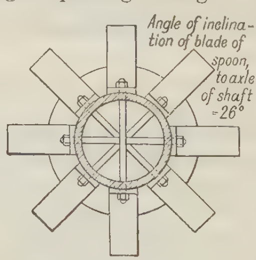

Fig. 5.—Cast-iron log.

Fig. 5 is a section of a log made of cast-iron pipe 11.5 in. diameter, 0.75 in. thick, flanged at both ends for attachment to the gudgeons. The blades are arranged 45° apart on two

spirals starting 180° apart on a 5-ft. pitch. The foot of each blade has two holes for 0.75-in. bolts. The arrangement of blades is such as to bring those in the two spirals at opposite ends of the same diameter every 5/8 ft. along the pipe and hence through bolts can be used, each pair holding two blades.

Structural-steel logs have been built in various forms. The principal difficulty is to effect secure attachment of the blades.

Feed is introduced on the upcoming side of single logs or between double logs and near the lower end of the trough, water is fed near the upper end; mud and fine sand are carried by the water over a weir (*b*) (Fig. 3) at the lower end while lump material and coarser sand are scraped up the trough and discharged at the upper end. Maximum size of feed is usually about 3-in.

Capacity varies with the size and speed of the log and the pitch of the spiral and is greatly affected by the character of feed. With easily washed ore of high specific gravity a double-log washer with 30-ft. × 7-ft. trough will handle about 500 tons per 24 hr. With difficult clayey ore a 20-ft. × 4-ft. trough may not handle over 50 tons of feed per 24 hr. Water consumption is from 4 to 8 tons of water per ton of solid. Power for double 25-ft. logs is about 25 hp. Treating manganese ores (*Bul. 734 USGS 99*) a double 25-ft. log making 12 to 15 r.p.m. treats 40 to 50 tons per 24 hr. with a consumption of 50 to 75 gal. water per min. and 20 to 25 hp.

Turbo washers are log washers with perforated false bottoms through which water is forced under pressure. They wash the lump material more thoroughly than the ordinary log washer does.

Mechanical classifiers (Sec. 6) are sometimes used as washers when the granular material is smaller than, say, 1-in, maximum size, and little or no disintegration is necessary.

5. Vertical-current washers

These machines are essentially hydraulic classifiers. They are satisfactory concentrators in the places in which they are used only because the service is relatively easy, such as the separation of clay and fine sand from lump iron ore; or because the amount of cleaning to be done is relatively small, as in the removal of slate from sized coal in the Draper washer; or because of repeated treatment, as in the Rheolaveur.

Wetherbee iron-ore concentrator (Fig. 6) combines mechanical agitation with free-settling hydraulic classification to effect separation of fine silica and clayey material from coarse and fine hematite in Mesabi wash ores. It is, therefore, a direct competitor of the log and turbo washers. Feed passing a ½-in. aperture is introduced into the revolving tub (*a*) and discharged by centrifugal force through the holes (*b*) into annular space (*c*) through which a current of water is rising. The theory of the machine is that the swirl in this annular space is sufficient to keep the lighter particles in suspension and that consequently a small rising current will lift them into the overflow, while the heavier particles will settle into the hopper-shaped bottom from which they may be removed by a drag or screw conveyor, or, if sufficiently fine, by a pipe-and-plug spigot.

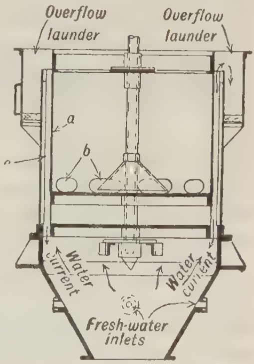

Fig. 6.—Wetherbee concentrator for wash iron ores.

Machines 3 ft. and 6 ft. in diameter have been used. Working on one particular ore, 28 r.p.m. for the 6-ft. machine and 36 r.p.m. for the 3-ft. machine were found to be the best speeds and hydraulic water consumption was from 80 to 150 gal. per min. The 6-ft.

machine readily treated 50 tons −½-in. feed per hr. and produced concentrate assaying 57 to 62 per cent. Fe from feeds carrying 39 to 54 per cent. Fe. Comparative results on two Mesabi mills, one using the Wetherbee machine and the other a turbo washer and tables to treat log-washer tailing, showed 81.4 per cent. recovery with a concentrate assaying 59.8 per cent. Fe for the first mill and 78.6 per cent. recovery with 58.8 per cent. Fe in the concentrate for the other *(103 J 301)*.

Draper tubular washer (Fig. 7) is essentially a hindered-settling classifier used for treating −⅜-in. sized coal. The usual size splits in British practice *(67 IME 502)* are −⅜ + 3⁄16-in., −3⁄16 + 1⁄16-in., −1⁄16 + 1⁄32-in. and −1⁄32-in. In one English plant the capacities at different sizes were −⅜ + 3⁄16-in., 6 tons per hr.; −3⁄16 + 1⁄16-in., 4 tons per hr.; −1⁄16 + 1⁄32-in., and −1⁄32-in., 1 ton per hr. Six machines required 200 gal. water per min. Performance is given in Table 1.

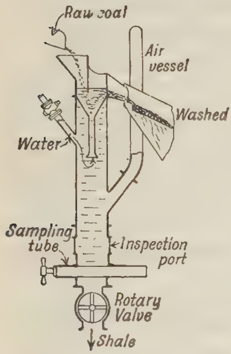

Fig. 7.—Draper coal washer.

Table 1. Performance of Draper washer

Size of feed, inches	Percentage ash		Free coal in refuse, per cent.
	Feed	Washed coal	
−⅜ + 3⁄16	16.8	3.8	0.25

−1⁄16 + 1⁄32	22.0	4.7	1.6
−1⁄32	29.7	9.1	3.2
Average	....	4.7	....

Rheolaveur (Fig. 8) is essentially a shallow-pocket launder-type classifier (see Sec. 6, Arts. 2 and 3) applied to the separation of impurities from raw coal. At sizes below 3½-in. separation depends on three different phenomena, *viz.:* (*a*) stratification, by reason of difference in specific gravity, which takes place in a substantially horizontal rapidly-moving stream in the trough and results in a layer of pyrite and slate at the bottom, bone above and coal on top; (*b*) difference in rate of movement along the trough, due to difference in shape, difference in specific gravity and difference in stream velocity at different depths, resulting in relatively rapid movement of the rounded, light coal particles in the rapid upper portion of the stream and relatively slow movement of the flat, heavy slate particles at the bottom; (*c*) difference in settling velocity in water due to difference in size and specific gravity. Thus when a mixture of particles is first introduced into the classifying trough, stratification occurs; thereafter the lower layer of slate moves less rapidly than the upper layer of coal and when a discharge slot (Fig. 9) is reached and support is taken away from all the particles, the resultant path of the large slate particles, having the greater instantaneous vertical acceleration and the smaller horizontal component of velocity, fall through the slot, if everything is properly proportioned, while the particles of coal and finer particles of slate pass on.

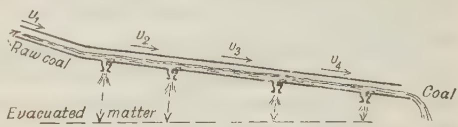

Fig. 8.—Rheolaveur.

Four different types of slate-discharge spouts are shown in Fig. 9. The form (A) is used for feeds coarser than ¼- or 5/16-in. The flap-valve (v) is arranged so as to open mechanically at short intervals, permitting slate to bank above it during the time that it is closed and remaining open only long enough to drop the accumulated slate without permitting coal to drop. An intermittent mechanically-controlled slate-discharge valve (Fig. 9, E) is attached to the bottom of the sorting pocket. Starting with chambers (A) and (B) full of water and valves (R_2), (V_1) and (V_2) closed, (valve (R_1) corresponds to valve (R_1) in Fig. 9, A), slate settles into chamber (A), displacing an equal volume of water upward through the sorting column, and collects for a predetermined time until (A) is partly full. Valve (V_1) is then opened, the slate falls into chamber (B), displacing water upward into (A) so that, again, no down current is induced in the sorting column. (V_1) is then closed, (V_2) opened, the slate discharged, and, after (V_2) closes, (R_2) opens and the water lost is replaced, a suitable vent for air being provided. A flap-valve slate discharge without rising current, discharging into a bucket-elevator boot tank (see Fig. 9, B) is used for later discharge ports. For fine material (−¼-in.) the continuously discharging spigot, Fig. 9, C, is used for the first slate discharges and the form, Fig. 9, D, without rising current, for the later pockets. The intermittent discharge (Fig. 9, E) may be attached to either of these, if the amount of water leaving with the slate is too great.

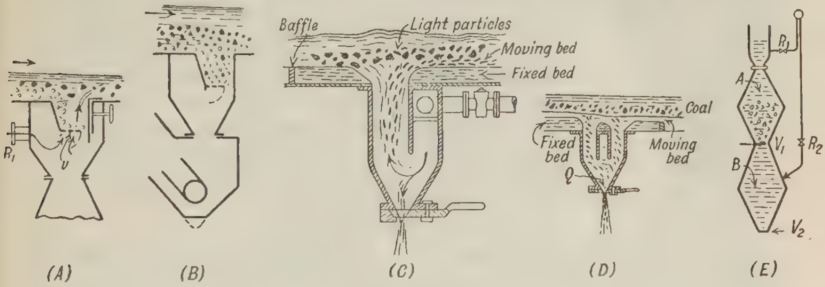

Fig. 9.—Discharge spigots, Rheolaveur.

Troughs are usually sloped 1 in 10 to 1 in 5 at the feed end, diminishing to 1 in 20 at the discharge end. A rising current may or may not be maintained in the sorting pockets. When feed is finer than 0.3- to 0.4-in. diameter, continuous discharge from sorting pockets is maintained, but for coarser feeds, up to 4-in., intermittent discharge, controlled by a mechanically-operated flap valve in the bottom of the trough, is used, with a constant supply of hydraulic water under the valve. When the valve is opened the upward rush of water prevents coal from falling.

As is true of all classifiers, clean separation on unsized feed is impossible. Hence in installing the process provision is made to take a coal-bearing middling from the sorting pockets of a primary machine, using low-velocity water currents, and clean coal from the later pockets and overflow end; then retreating the middling in a secondary machine with strong rising currents, making clean tailing and boney coal, the latter being returned to the head of the primary machine.

Considerable fine coal (−10- to 20-mesh) is necessarily lost with fine shale and clayey material that goes with the coarser coal and must be separated in the dewatering apparatus.

Capacity of 100 tons −3½-in. raw coal per hr. is claimed for a 2-spigot machine, with trough 1 ft. 8 in. wide by 16 ft. long, with a power consumption of 25 hp. for pumps, elevators and conveyors.

At Ormonde Colliery near Derby, England (*25 CA 455*), treating 100 tons per hr., the power consumed is 1 hp.-hr. per ton; the net water consumption 40 gal. per min. The refuse contains between 0.9 and 1.7 per cent. free coal while the ash content of the washed coal, including sludge, is in general not more than 2 per cent. in excess of the fixed-ash content. Sulphur is reduced from 1.6 to 1.1 per cent.

6. Tank washers

General. The principle of these machines is to agitate a mixture of minerals of different specific gravities in a tank containing a fluid which, either by reason of its density or the direction and velocity of its motion, causes the lighter mineral or minerals to float while the heavier sink. Tank washers such as the Robinson and Howe have been used for a long time in bituminous-coal washing, and the Chance washer is being used on both anthracite and bituminous coals. A considerable number of attempts have been made, as recorded in the patent office, to apply heavy-solution separation to southern hematite washing, but the high cost of solutions is a bar to commercial success.

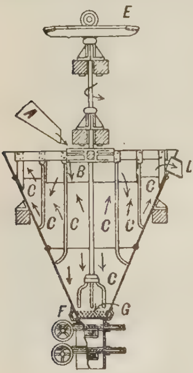

Fig. 10.—Robinson tub washer.

Robinson washer (Fig. 10) is essentially a hindered-settling hydraulic classifier (Sec. 6, Art. 3) with a stirring mechanism to prevent the material in the teeter chamber from packing and channeling. It is used to separate coal from slate and other heavy impurities. Hydraulic water enters through holes (G) from the annular pressure chamber (F) and rises with decreasing velocity through the cone to the overflow lip (D). Feed enters through the central ring (B), slate, pyrite, etc., settle against the rising current and are drawn off intermittently through the discharge valve at the bottom, while coal overflows.

A common size in bituminous washeries is 10½-ft. diameter by 10½ ft. deep with overflow lip 2 ft. long. The speed of the spindle is 20 to 25 r.p.m. Rated capacity on −3- or 3½-in. feed is 50 tons per hr. Water consumption is high and all fine dirt goes into the coal, but this can be separated by subsequent screening. Performance on different sizes of coal is shown in Table 2.

Howe washer is similar to the Robinson washer, except that the stirring arms are horizontal.

At Renton Coal Co., Renton, Wash. (*28 UW 104*), a Robinson washer treated −2½-in. raw coal containing 19.3 per cent. ash and made an overflow product containing 18 per cent. ash and refuse containing 61.5 per cent. Recovery of combustible was 97.3 per cent.; ash reduction, 6.7 per cent.

Hydro-separator (Fig. 11) is essentially a hindered-settling classifier. Feed entering behind the baffle (A)

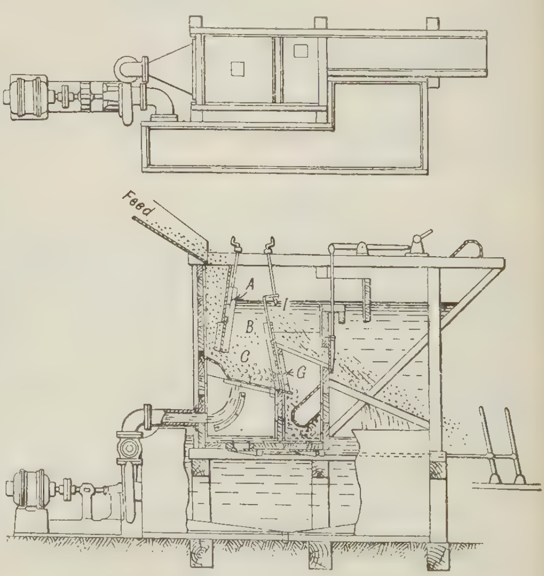

Fig. 11.—Hydro-separator for sized anthracite.

into the bottom of the sorting compartment (*B*) meets a rising current of water entering through perforations in (*C*) and the light material rises to the

a Solution, 1.35 sp. gr.

top of the teeter column and overflows baffle (*I*). The heavy material is withdrawn through an adjustable slot (*G*). The feed must be closely sized.

At Pennsylvania Coal Co., Dunmore breaker, (*26 CA 188*), three of these machines with screens 18½ × 24 in. treat 15 tons per hr. each of No. 1 buckwheat, rejecting about 2¼ tons of refuse containing about 6.7 per cent. coal, of which about half is bone. The cleaned coal contains about 7 per cent. slate. Each machine is served by a centrifugal pump delivering 320 gal. of water per min. against a pressure head of about 2 lb. and driven by a 3-hp. motor.

7. Heavy-fluid washers

These machines embody classification carried to the limit where, by reason of the fact that the density of the separating medium is greater than that of one of the ore constituents, the downward component of velocity of that constituent is zero. The processes differ in the character of the separating fluid.

Chance washer. Chance (*patent* 1,224,138/1917), describes a method of treatment of crude coal and certain ores in which the minerals of different specific gravities are caused to sink or float by gravity or by centrifugal force in a fluid mass of intermediate specific gravity, obtained by suspending finely divided solid matter in a liquid, usually water, by agitation.

Normally the separating chamber is a conical tank 6 or 15 ft. diameter provided with stirring arms on a vertical spindle and supplied at the bottom with hydraulic water. The lighter material overflows the periphery or is skimmed off while the heavy material is removed from the bottom by a drag conveyor or bucket elevator or by gravity through an intermittent slush gate. The pulverized solid whose suspension raises the apparent specific gravity of the fluid mass should consist of particles smaller than the average size of the particles to be floated and of greater specific gravity. Maintenance of the predetermined specific gravity of the fluid mass is the important and difficult part of the operation, since the added solid is lost by overflow and the liquid becomes contaminated by fine particles of both the sink and float materials. In patent 1,392,401/1921, it is claimed that specific gravities of 1.50 to 1.70 can be maintained with ordinary quartz sea sand and water. The size of feed is relatively unimportant from the theoretical point of view, but practically fine material is difficult or impossible to separate.

The method has had considerable trial in coal separation but none in metal concentration. In coal separation, quartz sand is used as the separating solid and water as the suspending liquid.

In patents 1,392,399 and 1,392,400/1921, Chance describes a method of maintaining a mass of water above the mass of suspended sand, thus furnishing a means of overflowing or washing off floated coal and also slime and organic waste in the feed. The overlying body of liquor also lessens the submergence of the mass floating on the dense-fluid mass.

In patent 1,392,401/1921, Chance and Chance describe the application of the heavy fluid mass obtained by solid suspension to the operation of jigs, classifiers, trough washers and the like. It is pointed out that in a fluid mass of 1.25 specific gravity the relative weights of coal (sp. gr. 1.30), boney coal (sp. gr. 1.45) and slate (sp. gr. 2.00) are 6⅔, 25⅔ and 100 respectively while in water the corresponding weights are 30, 45 and 100. Separation by settling is correspondingly easier in the heavy fluid. In 1,462,881/1923, Chance describes the use of a mixture of comminuted solids of different specific gravities, maintained by agitation, in order to get liquid masses of closely-stepped differences in specific gravity with any desired interstitial volume. If a liquid mass is desired with specific gravity = 2.00 and with 60 per cent. interstitial volume, to be made of water and comminuted solids of 2.5 and 5.0 specific gravities, it can be made by using 24 per cent. of the light and 16 per cent. of the heavy solid by volume. $(0.60 \times 1.00 + 0.24 \times 2.5 + 0.16 \times 5.0 = 2.00.)$ To obtain a fluid mass of the same density using water and the heavy solid alone would require 75 per cent. interstitial volume and such dispersed solids are

hard to maintain uniformly suspended. The minimum efficient interstitial volume is about 55 to 60 per cent.

In patent 1,556,676/1925, Chance describes the use of a fluid mass sufficiently dense to float middling and an apparatus with overflows at two or more levels to remove products of different specific weights.

In patents 1,559,937 and 1,559,938/1925, are illustrated two forms of apparatus for practicing the Chance process.

In patent 1,561,909/1925, Chance suggests a method of increasing the specific gravity of the fluid mass without decreasing its fluidity by introducing a second fluid mass, containing finer solid in suspension, so that it will rise through the first. Thus, if a separating fluid mass consists of 40 per cent. quartz sand and 60 per cent. water, the specific gravity is $0.40 \times 2.65 + 0.60 \times 1.0 = 1.66$. This is substantially the practical limit of density with quartz sand. If, instead of water a fluid mass consisting of 20 per cent. fine quartz sand and 80 per cent. water be injected to maintain dispersion of the coarser sand (the density of the secondary fluid being $0.20 \times 2.65 + 0.80 \times 1.0 = 1.33$), the density of the resulting composite mass is $0.40 \times 2.65 + 0.60 \times 1.33 = 1.858$. Chance suggests the possibility of using, say, a 10 per cent. suspension of fine magnetite ($0.10 \times 5.0 + 0.90 \times 1.0 = 1.40$) as the secondary fluid, in which case the specific gravity of the mixed fluid is $0.40 \times 2.65 + 0.60 \times 1.40 = 1.90$.

Arrangement of a Chance washer with coal and refuse screens and sand-recovery system is shown in Fig. 12. Sand is maintained in suspension in the

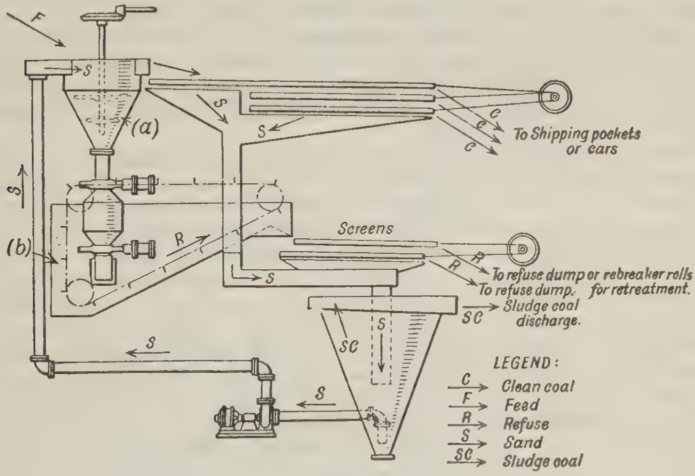

Fig. 12.—Arrangement of Chance washer.

washer (*a*) by means of the agitator and of water introduced at the apex. Raw coal is introduced at (*F*), the washed coal overflows with some sand onto a fine shaking screen which removes sand and this returns to the sand sump. Refuse discharges through the refuse valve into refuse tank (*b*) which likewise is discharged over a screen that sends sand to the sand sump. Fine coal and dirt overflow the sand sump and sand is returned to the washer.

The ratio of diameter of classifier column to diameter of the cone at the overflow level is determined by the density to be maintained and the sand used. The classifier column must be small enough so that, with sufficient water rising to maintain the desired density, the rising velocity in the column will prevent sand from settling. Hence the higher the density to be maintained and consequently, the less water introduced, the greater the necessary ratio between overflow and column diameters. If the large volume of water required for the low-density sand-fluid for bituminous-coal separation produces too great rising velocity in the classifier column to permit small slate particles to settle, part of the water

may be advantageously introduced through a manifold entering the sides of the cone at a number of points.

The Chance machine has been installed at several anthracite breakers. According to Chance (*70 A 743*) the capacity of a 7-ft. 8-in. (diam.) cone is 60 tons per hr. of fresh-mined coal or 30 tons of culm-bank material. The overflow capacity of this machine is about 50 tons per hr. (*21 CA 735*) hence this is the limiting factor on mine coal while slate-valve capacity is the limiting factor with culm. At the Nanticoke plant of Staples and Bell the average capacity on anthracite was 25 tons per hr. but the machine could be pushed to handle 60 tons per hr. The corresponding capacities of the 15-ft. cone are 200 and 150 tons feed per hr. The machine handles unsized feed from egg size down, although separation is poor below ⅛- to ¼-in., and this material should be removed in order to prevent contamination of the sand therewith.

Speed of agitator in a 7-ft. 8-in. cone treating anthracite is about 14 r.p.m. Power required in one installation (*21 CA 735*) was 11 to 16 hp. for agitator, refuse conveyor and screens and 20 hp. for the sand pump.

Sizing tests of feed and products of a machine treating run-of-mine and culm-bank anthracite are shown in Table 3.

For performance in bituminous washing see p. 63.

Conklin separator (*66 A 458*). The separating fluid consists of −200-mesh magnetite in water in the proportions, approximately, of 4.4 parts water to one of magnetite, which produces a fluid of about 1.9 specific gravity. The claimed advantage over the Chance process is that the magnetite fluid does not require agitation to maintain suspension and it is more readily separated from the products. The separating tank is rectangular, about 15 ft. long, and 8 to 10 ft. deep, while the width depends on the capacity desired, reckoning about 7 tons per hour per ft. Coal is removed by a chain drag while the slate is taken out by a screw conveyor.

Heavy solutions. The processes suggested may be classified as (1) pure gravitational settling in heavy solutions; (2) gravitational settling following treatment of the feed in such a way as to alter its effective specific gravity.

The basic requirements for a suitable heavy liquid are that it shall not react chemically with any of the constituents of the ore, which would result in irretrievable loss of solution; that it shall not, as a contaminant of the concentrate, interfere with subsequent use of the latter; and that it shall be cheap.

Most of the patented processes claim ability to treat ores in general, but economically, except in special cases such as flotation of wad or of coke, the various processes are applicable only to coal washing, where one of the constituents of the mixture to be treated has an exceptionally low specific gravity.

Pure gravitational settling in heavy solutions is an attractive idea, but fails commercially on account of the cost of solution and the impossibility or expense involved in so operating that there is little or no loss of solution with the products. There are a number of solutions capable of floating lighter minerals such as coal, *e.g.*, zinc chloride in water, but none that do not react with the coal are cheap enough. Various patented expedients suggested are:

Lurie (454,116/1891). Use of water and a liquid insoluble in and heavier than water, and also heavier than one mineral but lighter than the other, *e.g.*, (1) a liquid (sp. gr. nearly 4) made by distilling a mixture of bromine and alcohol, collecting the retort residue and decomposing with caustic alkali. (2) Tetrabromethane. (3) A liquid made from (1) by treating with pure acetylene (sp. gr. about 2). (4) Methyl-propyl-benzene or cymene in alcohol. Intermediate specific gravities may be obtained by mixing any two or more of these liquids.

DuPont (994,950/1911). A process for coal-slate separation in which after separation in a liquid of intermediate specific gravity (carbon tetrachloride) the floating material and separating fluid are then run into a liquid which has a higher boiling point than the separating fluid and is substantially immiscible therewith (water), and the separating fluid is volatilized and collected while the coal collects in the water. (1,002,865/1911) A method of separating limonite from silicious impurities, consisting in heating to change the iron to Fe_2O_3 and then separating in antimony bromide at 100° C. Addition of ammonium

chloride with antimony chloride prevents decomposition and insures complete volatilization (1,004,815/1911).

Stannous chloride (sp. gr. 2.27) liquefying at 114° C. may be used (1,064,459, 1,067,410/1913).

Nagelvoort (1,244,885/1917). The separating fluid may be removed by a volatile solvent and recovered by evaporation. Carbon disulphide is a suitable solvent for tin and arsenious bromides.

Gravity settling following change in density. The usual method for effecting density change is to heat. This may drive off water or otherwise increase the specific gravity of one of the constituents, *e.g.*, limonite, or it may render one of the minerals porous and thus decrease specific gravity, *e.g.*, pyrite. Another method is to coat the ore constituents, to a substantially like degree, with a substance, usually liquid, that is lighter than any of the constituents, thus rendering the lighter more easily floated while the heavier is affected less in proportion. The ideal condition would be to coat the light mineral preferentially.

Moxham (1,151,117/1915). Sulphuric and phosphoric acids are named as coating liquids and arsenic bromide, antimony bromide, bromoform, and tungsten solutions as separating mediums. (1,203,897/1916.) Calcining silicious iron ores in a neutral atmosphere to prevent reduction of the iron-bearing compound, since the reduced portion will react with bromides of antimony, tin or acetylene. (Sp. gr. of antimony bromide is given as 3.65 at 94° C.; tin bromide, 3.30 at 28° C.; acetylene bromide, 2.98 at ordinary temperatures.)

(1,294,519/1919.) Coating with a cheap liquid such as manganese bromide, zinc bromide or phosphoric acid before separating in an expensive liquid like arsenious bromide.

MISCELLANOUS SINK-AND-FLOAT PROCESSES

Separation of wad (1,277,144; 1,277,145/1918). Feed the pulverized ore to the center of a circular conical tank with a stirring apparatus that produces upward and outward currents. The porous manganese dioxide is floated over the periphery and the heavier material sinks.

Separation of metalliferous ores (386,504/1888). Use a liquid insoluble in and heavier than water but lighter than the rocky gangue of an ore, *e.g.*, carbon bisulphide, chloroform and oil of cloves on which, when submerged in water, the gangue minerals will float and in which "metals" will sink.

The principle involved here is not simple gravity settlement but a surface-tension phenomenon superimposed thereon, the effective forces causing flotation of the gangue being gravity of the liquid and resistance of the rocky material to wetting by the organic liquid.

STREAMING WASHERS

General. These washers are controlled applications of the typical phenomena of water flow on the earth's surface. The principles underlying these phenomena are: (*a*) The scouring or suspending action of a flowing stream on solid particles is in inverse relation to their weight, hence a stream of a given velocity will take light-weight particles of a given size in suspension and leave behind heavy particles of the same size. (*b*) The effect of a stream flowing down an inclined surface in moving particles not suspended along that surface is dependent upon the velocity of the stream. Velocity is least at the bottom and greatest at the top, hence the larger particles are acted upon most vigorously and, if they are just moved, the smaller unsuspended particles will not be moved. The resistance of the smaller particles to motion is enormously increased by roughness of the supporting surface, especially when the surface inequalities are the same size as the particles or larger. (*c*) In a mixture of particles of different sizes, sufficiently agitated to be semi-fluid, the smaller particles will work down through the interstices of the larger.

8. Pan

Description. The gold pan (Fig. 13) is used for prospecting gold-bearing detritus, for small-scale working of rich placer deposits, and for testing work in connection with gravity concentration. It is made of stiff sheet iron with the rim turned around a heavy iron wire for stiffness. Enameled-iron pans have the advantage of not rusting, but chip easily. Amalgamated-copper pans have been used for cleaning up black-sand concentrate. The usual size is 15 to 18 in. diameter at the top, 2 to 2½ in. deep, with the side inclined 30° to 80° to the bottom. Wilson recommends a 10-in. pan for prospecting. The weight is 1.5 to 2 lb. The inner surface should be smooth, and be kept free from grease and rust. A pan will save particles varying considerably in size, but for best work the heavy particles should average smaller than the lighter waste.

Manipulation. See Sec. 22, Art. 9.
When panning gold gravel as a concentrating as opposed to a testing operation, if there is much heavy sand present, it is best not to attempt complete separation with each pan, but to collect and later work up together the concentrate from many pans. In such work black sand (magnetite) may be removed (best dry) with a magnet and the gold, if amalgamable, may be collected with mercury, although this is not commonly done. Otherwise careful panning or blowing is necessary to make the final separation. In prospecting work when it is necessary to collect the gold from each pan separately, the quickest method of collection is to draw the colors into a head and then pick them out separately with a sharp-pointed metal or wooden tool. When there is a quantity of gold in the heavy sand, sizing in a series from 20- to 90-mesh before attempting final separation is helpful (*20 IMM 197*).

Fig. 13.—Gold pan.

Fig. 14.—Batea.

Capacity. The charge for a pan 16 to 18 in. diameter is from 15 to 30 lb. of ordinary gold gravel. Such material averages about 135 lb. per cu. ft; hence 243 @ 15-lb. pan loads = 1 cu. yd. A skillful worker can pan 100 charges in 10 hr.; gravel containing many boulders works more rapidly and fine or cemented gravel at about 75 per cent. of the rate stated.

Batea (Fig. 14) is an equivalent of the pan, used in Central and South America and in certain Asiatic countries. It is usually made of wood, less frequently of sheet iron. It is claimed that the wooden surface is superior to iron for catching and holding fine gold. *Bowie* states that Honduras mahogany is the best wood. The usual size for prospecting work is from 15 to 20 in. diameter with an angle of 150 to 155° at the apex of the cone, making the depth at the center from 1⅝ to 2½ in. Bateas 30 to 36 in. diameter are used in diamond washing in Brazil and in washing tin gravels in the Dutch East Indies.

9. Rocker

Rocker (Fig. 15) is used in the same kind of service as the pan, but has somewhat greater capacity. Rockers are of many designs and sizes but all consist essentially of a screen box (*a*) for rejecting coarse pebbles, an inclined apron (*b*) serving the double purpose of transporting undersize to the head of the rocker trough and of catching gold, and an inclined riffled trough (*c*) with flaring sides; all mounted on two rockers (*d*). The screen box may be provided with a handle (*e*) which serves both as an aid in lifting out and a grip for the operator in rocking, or the rocking stick may be longer and attached to the side of the trough near the head end. The SCREEN BOX ranges from about 12 × 12 in. in small prospecting rockers to 20 × 24 in. in large working rockers. It is sometimes made with a low side at the head end and the bottom inclined slightly toward the low side, in order to effect continuous discharge of oversize. The screen is occasionally a grizzly, but better perforated steel

plate, 10- to 18-gage, according to the service. The screen aperture depends to some extent on the character of the gravel; it varies between ¼- and ¾-in., normally is about ½-in. Percentage of opening should be as great as possible. The APRON is normally made of canvas tacked onto the frame in such a way as to leave a slight belly. Rubber sheeting backed with canvas (*93 J 1266; Peele 756*) and galvanized iron have been used. The slope of the apron is from 1.5 in per ft. upwards. The TROUGH proper is usually between 12 and 18 in. wide at the bottom and 3 to 6 ft. long, with slightly flaring sides from 1 to 2 ft. high at the deepest part. The bottom piece should be clear, soft lumber that will not shred or "rough-up" when wet under the action

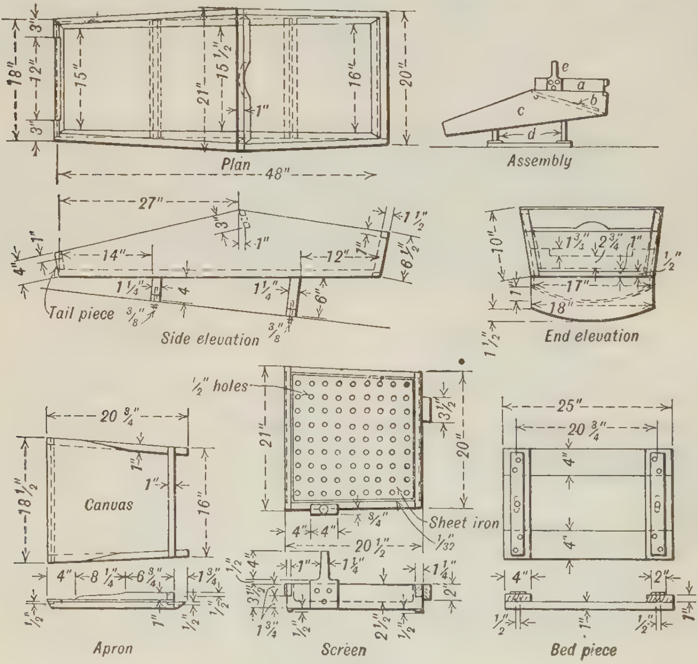

FIG. 15.—Rocker.

of the gravel. The slope of the trough ranges from 0.5 to 1.5 in. per ft. RIFFLE CLEATS of wood ½ × ½-in. to 1 × 1-in. are placed on the bottom of the trough and held down by strips nailed to the sides. The arrangement varies. Usually all are transverse but occasionally the upper half of the trough is riffled longitudinally. Canvas or blanket is sometimes used to cover the bottom and either may be covered with riffles made of expanded-metal lath. The TAIL PIECE at the lower end of the trough is usually between ¾ and 1¾ in. high at the center and from 1 to 3 in. higher at edges. It serves to hold a bed in the trough. The ROCKERS should have no more curve than is necessary to effect distinct agitation of the material in the machine; more makes the labor of rocking unduly fatiguing without any corresponding gain in concentrating efficiency. Dressed 1-in. lumber is heavy

enough. The joints should be tight. Warping may be prevented by light tie rods and the use of light-weight metal corner straps.

Manipulation. Material is shoveled into the screen hopper and washed by means of water poured in from a dipper. At the same time it is forked over and disintegrated and coarse clean boulders are thrown out. More water is then added slowly and the machine is rocked in such a way as to cause material to progress along the floor of the trough, to loosen the bed at each stroke, and to maintain even transverse distribution of the solids. *Wilson* states that one swing should be sharper than the other, to effect stratification, or even that a bumping block may be used, but either procedure will cause heaping of solids and concentrate at one side of the trough with consequent difficulty in manipulation and loss of values. When the deposit of gold has worked down to near the tail piece, or sooner if the exigencies of the operation demand, a clean-up is made. The material behind the tail piece is shoveled out, the screen is then carefully washed and removed, the apron lifted out, and the contents washed carefully into a pan for re-concentration. The riffles are taken out and carefully washed and the deposit in the trough is then washed on the plane bottom by streaming as described in Art. 11. Final clean-up is usually made in a pan.

The longitudinal progress of tailing depends upon slope, shake and wash water. Slope should be adjusted so that satisfactory longitudinal progress is effected with minimum consumption of water and energy and so that sand does not pack behind the tailboard and in the riffles. Slope must be steeper for a gravel containing much fine sand than for one of more pebbly character, likewise if much heavy sand (black sand) is present a steeper slope is necessary than otherwise. If gold is fine, the bed must be loose, hence a relatively steep slope is required.

Capacity varies with size. Purington (*Bul. 263, USGS*) gives 3 to 5 cu. yd. per 10-hr. day for 2 men working steadily, one feeding and removing boulders and tailing, the other rocking and washing. *Van Wagenen* gives 3 cu. yd. per 10 hr. per man in ordinary grave and 2 cu. yd. in cemented gravel. Capacity is less in prospecting work on account of more frequent clean-ups.

Water consumption varies widely, but from 50 to 100 gal. per cu. yd. treated is sufficient if the gravel is not too fine, slope sufficient, and water is used sparingly.

Applicability. A rocker catches coarse gold readily but will lose much fine gold. The loss will be greater with clayey or cemented gravel or if muddy water is used. In some cases quicksilver placed in the riffles will aid in catching fine gold, but since the loss occurs rather through failure to effect settlement of the gold than by washing it out of the riffles, this expedient is rarely successful. The rocker is rarely used except in sampling when a device of greater capacity than the pan is needed, and in cleaning up concentrate from sluices and gold tables.

North Carolina rocker consists of a semi-cylindrical trough, closed at both ends, with two longitudinal riffle cleats near the bottom. The charge with water is first rocked gently to effect stratification, then the apparatus is rocked differentially in such a way as to throw waste over the rim and leave the gold and heavy sands between the riffle cleats. Clean-up is made in a pan.

Mechanical rocker (*116 J 334*) driven by crank from a water wheel has been used to treat ordinary gravel at the rate of 5 cu. yd. per 8 hr. The trough was 14 in. × 12 ft.; the screen hopper sloped in the opposite direction from the trough and discharged oversize of a 0.5-in. screen automatically over a trifle.

10. Long tom

Description. The long tom (Fig. 16) has greater capacity than a rocker but requires more water. It consists of a sloping trough about 12 ft. long, 15 to 20 in. wide at the upper end, flaring to 24 or 30 in. at the lower end, with sides 8 to 12 in. high. A perforated plate with ⅜- or ½-in. holes, set level or slightly inclined is fitted at the lower end. The usual slope of the trough is 1 in. per ft. A wider and usually shorter trough with transversely riffled bottom, set on a flatter slope, follows the first and receives the undersize from the screen.

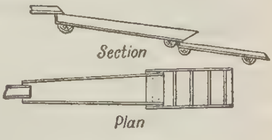

FIG. 16.—Long tom (*after Bowie*).

Manipulation. Gravel is shoveled into the upper trough and water is led in by a flume at the head end. The operator works the gravel over thoroughly, forks out the boulders

and works fine material through the screen. Coarse gold settles in the upper box and fine gold is caught behind the riffles in the lower trough. *Wilson* recommends that the slope of the riffled box should be so flat that fine mud will collect therein, thus insuring that fine gold is not scoured out, but this will result in sanding behind the riffle cleats to such an extent that their protective function for fine gold is defeated and the bottom will become merely a transversely undulating sandy surface.

Capacity varies with the kind of gravel and size of screen perforations and is limited by what a man can work through the screen. *Wilson* states it to be 6 cu. yd. of ordinary light gravel or 3 to 4 cu. yd. of cemented gravel per 10 hr. with 2 men working, one shoveling in and taking care of tailing and the other working the upper box. *Van Wagenen* gives 5 to 6 cu. yds. of ordinary gravel or 3 to 5 cu. yd. of cemented gravel per man per 10 hr., but this is undoubtedly too high.

Applicability. The long tom uses less water than a sluice (Art. 11) but at the expense of more labor. It saves a given amount of gold in a shorter linear distance. It has, therefore, been used in small-scale placer work where water and lumber were scarce, and has also been rather widely used on dredges for cleaning up black-sand concentrate. (*115 P 825, 113 J 251.*)

11. Sluice

Description. A sluice (Fig. 17) is a long, relatively narrow and deep inclined trough, usually with riffled bottom, through which gravelly material containing a small percentage of heavy valuable mineral is transported by water, with the result that the heavy material settles in the riffles and is held while the light is washed out at the lower end. Sluices have been used extensively in washing gold-bearing gravels in all parts of the world; much less extensively in working tin (cassiterite) placers, and occasionally for other service such as the recovery of metallic copper and brass from foundry refuse and the like.

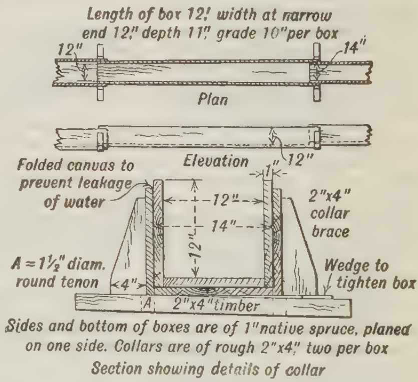

Fig. 17.—Sluice box.

The size and elaborateness depend on the scale of work. Sluices for prospecting and small-scale mining work are usually 12 in. wide and deep, made in 12-ft. sections, usually with sufficient flare to allow about 2 in. telescope in joining them together in strings. Some operators prefer butt joints with cover strips, on the ground that they cause less clogging than telescope joints. One-inch lumber is usually employed for sides and bottoms of small sluices and 2 × 3-in. or 2 × 4-in. scantlings for bracing (see Fig. 17). Such boxes will generally serve for a season (4 to 6 months), rarely for more than a year of continuous service. Sluices intended for permanent use are made with 1.5- to 3-in. bottom boards and bottom side boards and with 1- to 3-in. upper side boards; usually in 12-ft. lengths, the transverse dimensions depending upon the amount of solid and water to be transported, the slope or grade, and the character of the heavy mineral and gravel.

Water-carrying capacity. *Bowie* gives the following data: A sluice 6 ft. wide, 36 in. deep on 4 to 5 per cent. grade will run 3000 to 5250 cu. ft. of water per min.; 4 ft. wide and 30 in. deep, 1200 to 2250 cu. ft. per min. on a 2.1 per cent. grade and 3000 cu. ft. per min. on a 4 per cent. grade; 3 ft. wide, 30 in. deep, 900 to 1500 cu. ft. per min. on 1.5 per cent. grade. Assuming the wetted depth to be 50 per cent. of the total depth, which is usual,

these figures correspond to average water velocities in the sluice of from 4 to 10 ft. per sec. *Van Wagenen* states that the moving power of water in sluices varies with the velocity as follows: 16 ft. per min. begins to wear away fine clay, 30 ft. per min. just lifts fine sand, 39 ft. per min. lifts sand grains up to 1/16-in. diameter, 45 ft. per min. moves fine gravel, 120 ft. per min. moves 1-in. pebbles, 200 ft. per min. moves 2- to 3-in. pebbles, 320 ft. per min. moves boulders 3- to 4-in. in size, 400 ft. per min. boulders 6- to 8-in., 600 ft. per min., boulders 12- to 18-in. In all cases the depth of water must be sufficient to cover the largest particle to be moved. The bottom width should be 1.75 to 2.25 times the wetted depth for maximum water-carrying capacity.

The sluice boxes should be made thoroughly water-tight. The lumber should, therefore, be surfaced and sized, free from knots and cracks, but it need not necessarily be tongued and grooved. Sills and posts for large sluices are made of 4 × 6-in. or 6 × 6-in. lumber and spaced about 3 to 4 ft. apart. On every second or third set the posts should be braced to the sill with 1 × 6-in. or 1 × 8-in. angle braces and the sill should be about twice as long as the sluice width to give proper slope to the braces. The bottom and sides should be spiked to the sills and posts with 30d and 20d spikes respectively, spaced about 4 in. (*Bowie.*)

A large sluice used at La Grange mine in California is shown in Fig. 18 *F*. The sides, bottom and side liners are 3-in. plank. Rail riffles, set longitudinally in the head end of the sluice and transversely below, are used.

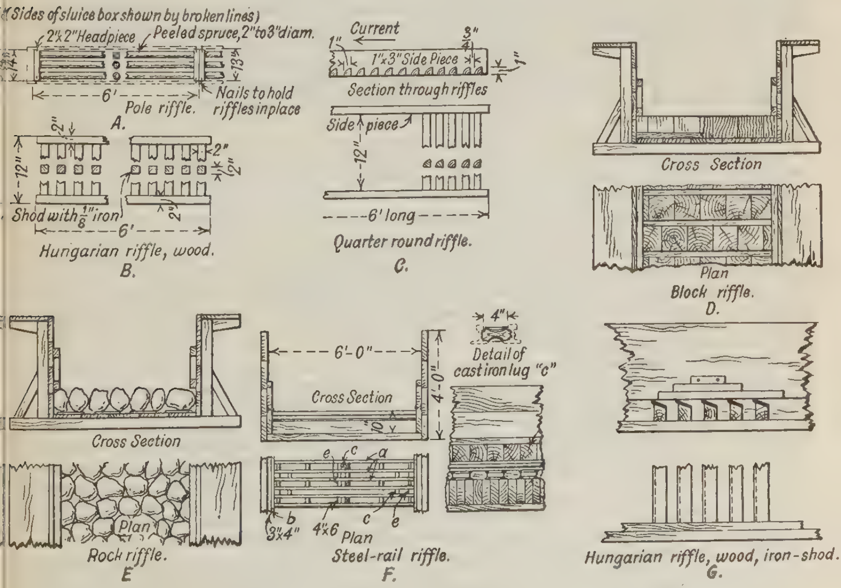

Fig. 18.—Riffles.

Australian practice differs (*17 MM 16*). Boxes for gold gravel are made 4 to 8 ft. wide, 12 to 15 in. deep, and 60 to 100 ft. long, in 12-ft. sections and are bolted together with flush joints and outside cover plates. Boxes for tin gravels are 10 ft. wide, 18 in. deep and 120 to 200 ft. long.

Riffles are placed in sluices to catch and hold concentrate and, to a minor extent, to disintegrate the gravel. They perform the first function by roughening the bottom surface of the sluice, thus decreasing the velocity of the lower

layer of water and permitting concentrate to settle readily. The interstices furnish protection to the settled material from the horizontal transporting effect of the stream. A secondary desideratum is a boiling action in the bed of settled material in the riffles, as a result of which the lighter material will be lifted out while the heavy particles remain. Disintegration is effected by tumbling of the solid as opposed to sliding.

Pole riffles (Fig. 18*A*) are probably the most common form for small sluices, when a maximum amount of material is to be moved with a minimum amount of water, gold is coarse and loss of a small amount of fine gold is relatively unimportant. They are made of 2- to 3-in. peeled poles or 3 × 3-in. squared strips spaced 1½ to 3 in. in the clear and made up in 6-ft. units by transverse straps nailed on at both ends. Pole riffles wear quickly but are inexpensive. Squared riffles are often protected by angle iron. The end straps are cut to fit snugly across the sluice box and are held in place by nails driven into the ends through the sides of the sluice. A somewhat similar riffle, made of 1.5 × 6-in. plank set on edge longitudinally, spaced by 1.5-in. blocks, and shod on the upper edge with an iron bar 1 in. × 1.5 in., is described by *Bowie*. Hutchins (*Bul. 263 USGS 200*) describes a pole riffle with 2 × 2 × 1/16-in. pieces of sheet iron driven into the poles cornerwise, long axis parallel to the poles, for use in disintegrating clayey material.

Rail riffles (Fig. 18*F*) are used in large sluices where resistance to wear is an important factor. They may be set lengthwise, in which case their action is similar to that of pole riffles; or they may be set transversely. Longitudinal-rail riffles are made up in 6-ft. lengths and the width of the sluice box. They are set bottom-side up and held together by special locking devices as shown. Bouery (*95 J 1055*) found that the life of rails set transversely was greater than with longitudinal setting, that between 4 and 6 in. center to center was the best spacing for transverse setting, considering both duty of water and gold saving; and that with longitudinal setting wear was more rapid with 8-in. spacing than with 5-in. He also found that when rails were set directly on the bottom of the sluice the gold-saving capacity was insufficient and therefore devised and used the combination riffling shown in Fig. 18*F*, in which the principal function of the rails is to protect the wooden riffles from wear and to increase the transporting duty of the water. 45-lb. rail riffles set longitudinally handled about 32,000,000 cu. yd. of water and 2,500,000 cu. yd. of gravel before replacement was necessary; the same weight rails set transversely handled 50 per cent. more material, with spacing in both cases 5 in. center to center.

Block riffles (Fig. 18*D*) are the commonest form in all large sluice lines. The blocks are usually about 8 to 13 in. long, either squared or round, 6 to 20 in. in diameter or on an edge. They are nailed to 1- or 1.25- × 2- or 3-in. cross strips before being put in place and these strips are nailed through the sides of the sluice. Holding-down strips nailed to the inner sides of the sluice are also used. Squared riffle blocks are usually spaced about 1 in. from face to face transversely (thereby differing from the figure) and the nailing strips produce a spacing of about 1 in. longitudinally. Longitudinal joints are preferably staggered in adjacent transverse rows. Round blocks are fitted as closely together as possible when fastening them to the nailing strip.

Block riffles produce a large amount of drag; they offer good protection to settled material and cause sufficient boiling to remove a considerable amount of sand from the concentrate. Their disintegrating effect is low, but, in compensation, they interfere but little with transport. *Bowie* advises the use of block riffles in the head boxes at all times. Their ADVANTAGES are: cheapness, efficiency in gold saving, ease of removal and clean-up; their DISADVANTAGE is rapid wear. At LA GRANGE, when handling 1000 cu. yd. of gravel per hr. in a 6-ft. sluice, the life of pine blocks was only 17 days (*95 J 1056*). *Bowie* states that nut- or pitch-pine or a wood that is long-grained and "brooms" readily is best and deprecates the use of oak or other hardwoods that wear smooth. Round blocks are more difficult to set than squared but may cost sufficiently less to be economical. Welton (*20 IMM 172*) criticizes block riffles on the ground that gold does not readily settle in them and that they absorb gold values. The first criticism is not in line with general experience. There is, undoubtedly, some catching of gold in interstices in the blocks themselves and old blocks should be and commonly are burned and the ashes panned.

Rock or stone riffles (Fig. 18*E*) are made by packing the bottom of the sluice with selected rocks, usually flattened, set on edge, inclined slightly with the run of the material and with the longer dimension transverse. They are prevented from shifting longitudinally by transverse poles nailed in at intervals. No devices for holding down are ordinarily necessary but with large quantities of coarse gravel they may become displaced. Rock riffles wear longer than block riffles and are more effective in breaking up cemented gravel but they are more expensive to set and to clean up. They also require more water and greater slope to handle a given quantity of a given gravel. Welton says that under conditions requiring 0.5 in. per ft. slope with block riffles, rock riffles will require 0.75 in. per ft. They are com-

monly used in California for a short distance at the head of the sluice line and also in the tail sluices following block riffles, where their principal function is as a chute liner and clean-ups are infrequent.

Rock for riffles should be hard and uniform in size and hardness. Quartz is probably the best material, if locally available. As between block and stone riffles, Welton states that the former will collect three times as much gold in a given length. He ascribes this to the fact that with the rocks there is no continuous bar formed across the sluice and that the gold, therefore, works along more readily and for longer distances.

Hungarian riffle. This name is used by different writers to denote different forms of riffles. Probably the nearest to a common characteristic in all riffles so named is an overhang on the down-stream side. Fig. 18*F* shows one form so made that the overhanging strap slopes upward slightly on the down-stream side. It is frequently claimed for this type of riffle that it is good for disintegrating gravel, but Perrett (*122 P 417*) rightly remarks that a sluice is not an efficient gravel disintegrator and that the use of obstructive riffles to effect disintegration results in undue loss of capacity. Riffles formed by gouging or boring out pockets in plank (PIT RIFFLES) are also called Hungarian riffles (*Wilson*) as are also transverse square riffles without overhang. (Fig. 18*B*, *100 J 995*.) PIT RIFFLES are used with mercury in the treatment of fine material. They are not suitable for coarse material on account of the fact that mercury and amalgam are splashed out of the depressions by impact of the large stones.

Miscellaneous riffles. A large number of other riffle forms have been used. Expanded metal over cocoa matting is common on dredge tables.

Moline (*17 MM 16*) describes several riffles used in Australian gold practice. A so-called Venetian riffle is used in certain parts of Russia (*15 MM 148*). The natural surface of bed rock or a bed-rock surface crudely riffled by cutting transverse gutters forms the first gold-catching surface in some hydraulic mines. The grade must be much greater (*Wilson* says twice) than that of a wooden sluice for the same material. Hutchins (*105 J 861*) describes the use of a riffle in a Siberian sluice, consisting of perforated plate with ¾-in. apertures, set 3 in. up from the bottom.

Blankets, corduroy, hides with the hair up, canvas, velvet, carpet, cocoa matting, and sod have all been used as gold-catching surfaces. For such surfaces the feed should not be coarser than 1- to 2-mm.

Comparison of riffles. It is impossible to classify riffles in other than most general terms with respect to their ability to perform their various functions. Riffles presenting a uniformly roughened upper surface of relatively fine texture have maximum retarding effect on the lower layer, but do not roughen the water surface, and roughening is desirable for catching fine gold. Transverse riffles forming a complete bar across the bottom of the sluice afford maximum protection to settled material and also cause considerable boiling, which enriches concentrate, but they obstruct the passage of gravel and consequently lower capacity. Longitudinal riffles cause the least drag on the lower layers of the stream and offer the least obstruction to the passage of gravel; they also offer minimum protection to settled material and are more subject to scouring action. The life of different types and the ease of removal and replacement are important considerations. In many cases the availability of a given riffle material or the prejudice of the operator is the deciding factor.

Slope of the sluice line depends on the character of the gravel, character of the gold, kind of riffles and quantity of water available. Flat and shingly gravel requires more slope than rounded gravel; coarse gravel requires greater slope than fine. Very fine gold may be carried in suspension in the water if the slope is steep and the velocity correspondingly high, especially if there is much clay or mud; on the other hand, moderately fine gold is best caught in "rough" water and this condition is obtained by steep slope. Obstructive and transverse riffles used for disintegrating clayey and cemented gravels require steeper slope than longitudinal or block riffles. Restricted water quantity demands steep slope, if the maximum quantity of gravel is to be handled. With a given amount of water narrow sluices require, of course, less slope than wide. As a general operating rule, the slope should be such that

the water used will transport the rocky material and prevent sand from packing in the riffles, but should not exceed this.

Bowie states that 6 to 6.5 in. per 12-ft. box is usual; 9 in. to 12 in. when much clay is present. Rounded gravel containing considerable clay or soil may be moved on a slope of about 2 in. per 12 ft. but it is better to have as much as 6.5 in. per 12 ft. to increase capacity and lessen the labor required for handling large boulders. Coarse gravel needs from 6 to 10 in. per 12 ft. and considerably more water than fine gravel. *Van Wagenen's* rule for slope for handling average gravel is: $F = V^2P/2A$ where F = fall in ft. per mile, V = velocity in ft per sec., P = wetted perimeter in ft. and A = area of stream in sq. ft. *Wilson* gives Chezy's formula for the velocity V in ft. per sec., necessary to transport boulders of average diameter a in ft. and specific gravity g as $V = 5.67\sqrt{ag}$.

Perrett (*122 P 417*) states that the shingly Siberian gravel, when unscreened, requires a slope of 18 in. per 12-ft. box. Sluices for treating tin gravels are usually set on flatter slopes, ranging from 4.5 to 6 in. per ft.

Length depends principally upon the character of the gold, less upon the dimensions and slope of the sluice and the kind of riffles. Coarse and granular gold settles quickly and is easily held in the riffles, fine and porous gold is carried long distances by the current.

The minimum length for relatively deep, narrow sluices is 500 to 600 ft.; the sluice line at some mines is several thousand feet long, but this great length is as often for transport of tailing to a suitable dumping ground as for saving fine gold.

Drops up to 12 in. in height in the line of boxes are of use in breaking up cemented and clayey gravel and in causing gold to settle in the riffles.

Curves lessen the velocity of the stream and cause deposition of solid matter with resultant clogging of the sluice.

Wilson recommends elevation of the outer edge 1 in. for every degree of curvature and an increase in slope for a short distance (2 or 3 box lengths) below the curve.

Mud box or **dump box** (Fig. 19) is frequently used at the head of a sluice line when material is fed in batches, as by horse scraper, drag-line or derrick

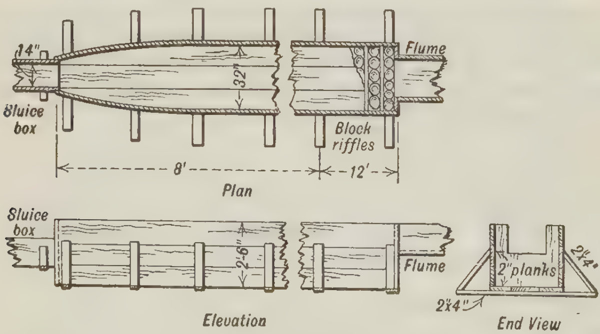

Fig. 19.—Mud box.

bucket or the like, and contains much clayey or cementing material, or when water is scarce. In it the material is worked over and disintegrated by means of a coarse-tined rake or fork and large boulders are removed. It may be riffled or not. If so, rock riffles are usual. The slope is steeper than in the main string, usually about 1 in. per ft. Much coarse gold is caught here and clean-ups should be frequent.

Undercurrent is a device used in connection with sluice lines to catch fine gold from the finer material fed to the sluice. In order to treat the mater-

ial in a thin film and thus get the turbulent current and small settling distance necessary for catching fine gold, the undercurrent is made wide; it must be made correspondingly steep in order that the water may have sufficient velocity to move the gravel. A perforated screen or a grizzly usually with ⅝-in. to 1-in. openings is set with its upper surface about 1 in. below the top of the riffles in the main sluice. The area and aperture of the grizzly must be such that the main sluice is not robbed of so much water that it will not carry the coarse tailing. Undersize is led off in a converging launder, with suitable distributing devices to spread the feed evenly across the width of the undercurrent. The latter is proportioned to the size of main sluice and the quantity of gravel carried.

The WIDTH is usually 5 to 20 times that of main sluice and the length varies from 20 to 50 ft. Welton (*loc. cit.*) recommends an undercurrent 20 ft. wide and 30 ft. long for a 4- to 5-ft. sluice. He also recommends dividing such an undercurrent by longitudinal walls into four sections, thus allowing three to be run while one is being cleaned upand re-blocked. This is a good arrangement, since the undercurrent must usually be cleaned up more frequently than the main sluice. The USUAL SIZE of undercurrent in Alaska for a 12-in. sluice line handling 400 to 500 cu. yd. per day is 20 ft. square. The SLOPE is usually about twice that of the main sluice; *Bowie* recommends 12 in. per 12-ft. box for longitudinal plank or pole riffles, 14 in. for blocks and 16 in. for stones. RIFFLES are placed both in the distributing launder and the undercurrent proper. They are of any of the varieties described. A common arrangement is to have blocks in the upper half and rocks below or longitudinal poles above and transverse poles below. TAILING is usually led back into the main sluice. The RETURN SLUICE should enter the main sluice at an acute angle and with little or no drop, in order not to interfere with the flow in the main sluice.

Recovery in undercurrents varies according to the character of the gold and the sluice treatment preceding. Welton says that an undercurrent following 500 ft. of sluice should make 10 to 15 per cent. of the total combined recovery. It frequently runs as low as 2 per cent.

Tables are short, wide sluices, usually set on a relatively steep slope, taking a finer feed than the ordinary sluice and usually operated with some mercury in the riffles. Their principal use is on gold dredges (see Sec. 2, Art. 19).

Hutchins (*105 J 861*) describes a table installation in Siberia where material through a 1-in. screen was treated on tables 10 ft. wide by 30 ft. long set on a slope of 2.25 in. per ft., the tailing after passing through a 0.5-in. screen passed over a similar set of tables on 2-in.-per-ft. slope, and this tailing after screening through a ¼-in. screen was sent over a similar set of tables on 1.5-in.-per-ft. slope. There were a few riffles on these tables, but sand packed behind the riffles and spoiled their usefulness. Very little gold was caught, most of it being caught in the sluice preceding the tables. It will be noted that this is an undercurrent installation.

Perrett (*122 P 417*) argues for tables as opposed to the ordinary sluice on the score of compactness, low water consumption and high gold saving. He cites a Russian plant with tables 38 ft. long on which 97.56 per cent. of the total recovery made was made on the first 10 ft., 1.95 per cent. on the following 14 ft. and 0.49 per cent. on the last 14 ft. The loss was 0.6 grain per cu. yd.

Water consumption is extremely variable.

Hutchins (*105 J 861*) states that ordinary cemented gravel from CALIFORNIA DRIFT MINES requires from 7 to 13 cu. ft. of water per cu. ft. of gravel and hard cemented gravel requires from 20 to 27 cu. ft. on the average. *Bowie's* figure for NORTH BLOOMFIELD, treating mostly top gravel in 6-ft. sluices with block and rock riffles on a slope of 0.54-in. per ft., is 18 cu. ft. of water per cu. ft. of gravel and at LA GRANGE, in a 4-ft. sluice with block riffles on a slope of 0.25 in. per ft., 56 cu. ft. Purington (*Bul. 263 USGS 142*) gives 40 cu. ft. of water per cu. ft. of gravel with block riffling on 0.33 in. per ft. slope under most favorable conditions in SOUTH-EAST ALASKA. In the ATLIN DISTRICT, B. C., with pole riffles on a slope of 0.67 in. per ft., 20 cu. ft. of water per cu ft. of gravel was used. At the Bowlder Creek mines of SOCIÉTÉ MINIÈRE DE LA COLOMBIE BRITANNIQUE a 24-in. sluice on a slope of 0.5 in. per ft., with block and rail riffles, required 80 cu. ft. of water per cu. ft. of gravel, of which 50 per cent. was boulders 18 to 30 in. diameter. A KLONDIKE bench-gravel sluice, 24 in. wide on a 1-in.-per-ft. slope, with block riffles, required 20 cu. ft. of water per cu. ft. of gravel. 12-in. sluices in ALASKA in shoveling-in work require 45 to 90

cu. ft. of water per min. Hutchins gives 80 cu. ft. of water per cu. ft. of gravel as an example of inefficient washing of clayey gravel in SIBERIA. Consumption on NEW ZEALAND GOLD DREDGES is given (*16 MM 81*) as 75 cu. ft., while on tin dredges about 20 cu. ft. is provided. Perrett (*122 P 417*) says that not over 33 to 40 per cent. of the amount of gravel can be washed in a sluice with a given amount of water that can be washed in a plant equipped for removal of oversize, with subsequent treatment on gold tables.

Operation consists in keeping gravel running through the sluice, undercurrent or table, until the riffles are so filled with concentrate that an excessive amount is going into the tailing, then cleaning up. The time between clean-ups depends upon the sluice and the character and quantity of gravel treated. Usually the head sluices are cleaned up at approximately regular intervals of one to four weeks, as dictated by experience, while the tail sluices are cleaned only once or twice per season and are depended upon to catch any gold that passes the head sluices by reason of too great an interval between clean-ups.

Cleaning up. The supply of gravel is stopped and clear water run until the tops of the riffles are clear of gravel. The riffles are then lifted out, beginning at the lower end of the first length of, say, 100 ft. of boxes, and washed carefully into the sluice. After all the riffles in a given section have been removed, a light flow of water, just sufficient to move the material slowly, is turned on and the concentrate is carefully and slowly turned over by means of wooden paddles 3 or 4 in. wide pushed upstream along the bottom. Rocks are thrown out by hand. Welton (*20 IMM 172*) describes a special clean-up shovel made of light sheet steel with flat bottom, sides turned up 1 in. and back sloping at 45° to the bottom. The shoveler faces down-stream to pick up a load and turns around and holds the shovel in the stream, when light material is washed over the back leaving rich concentrate on the shovel. As material works down-stream, a head of enriched material is left behind. This is carefully collected and further concentrated in a pan or rocker, with or without mercury, as circumstances dictate, or it may be brushed against a flat stone in the sluice, which serves as a planilla (Art. 13). (When the gold is amalgamated, iron or granite pails, not galvanized or tinned, should be used for collecting concentrate.) The next lower section is next treated in the same way, or, in some cases, concentrate from the lower sections is carried in pails to the head of the first section and there cleaned. Finally gold is collected from crevices by means of a pointed amalgamated-copper spoon. Considerable gold may get so far into crevices that it cannot be collected in this way. Such gold is recovered, when the sluice is worn out or the working is abandoned, by burning the sluices and panning the ashes. Ellis (*100 J 993*) states that some Alaskan boxes on burning have yielded as much as an ounce of gold.

The time required to clean up and re-block 100 ft. of 4-ft. sluice is about 4 hr. (*20 IMM 208*).

Heavy sand concentrate that banks up before the riffle at the lower end of the section being cleaned is collected separately and further concentrated in rocker or pan, or it may be sold or treated with mercury and cyanide in a tumbling barrel.

Distribution of gold in sluice. The bulk of the gold content of gravels settles to the bottom of the sluice with great rapidity and resists transportation with extraordinary tenacity.

Wright (*Gold Fields and Mineral Districts of Victoria, R. B. Smyth*) says that in a 12-in. sluice sloped 1 in 48, using 600 gal. per min., 95 per cent. of the gold was found within 3 ft. of the feed point, lying on a smooth board. *Bowie* states that at NORTH BLOOMFIELD 92 per cent. of the total yield was made in the first 1800 ft. of sluice, 3.75 per cent. in 6200 ft. of bed-rock sluice following, 2.5 per cent. in undercurrents. He gives considerable detailed data of similar import. Purington (*Bul. 263 USGS 142*) gives the following data: South Coast region of ALASKA, gold bright and rough though fine, mercury used in boxes, 75 per cent. saved in the first 600 ft. MCKEE CREEK, Atlin, B. C., slope 0.67 in. per ft., block riffles, gold coarse, 85 per cent. saved in first box, all that it pays to clean up saved in the first five boxes (60 ft.). At another mine in the district no gold is caught beyond the first 250 ft. of boxes. ELDORADO COUNTY, CALIFORNIA, slope 1.1 in. per ft., car-wheel riffles, mercury in the boxes; 75 per cent. of the total recovery was made in the first foot, 8.4 per cent. in the next 10 ft., 9.6 per cent. in the next 50 ft., and 2 per cent. in the next 60 ft.; slightly less than 5 per cent. of the total gold recovered was caught in 2380 ft. of rock-paved sluice following the first 1000 ft. BONANZA CREEK, KLONDIKE, gold fine, bright and smooth, 2-ft. boxes on 1-in.-per-ft. grade, block-riffled, 80 per cent. of total gold recovery was made in the first box, 85 per cent. in the first 180 ft., none in the last two boxes in the 500-ft. string.

Hutchins (*Bul. 263 USGS 190*) estimates that in small-scale Alaskan practice, shoveling-in to short strings (3 to 6) of 12-in. boxes set on about 0.5-in.-per-ft. slope, using pole riffles, about 80 to 90 per cent. of the gold fed is recovered but that most fine gold is lost. Bouery (*95 J 1056*) gives the data shown in Table 4 representing the distribution of gold in size and

Table 4. Distribution of gold according to size in La Grange sluice boxes. (*After Bouery*)

Box number	+ 10-mesh	− 10 + 50-mesh	− 50 + 100-mesh	− 100+150-mesh	150 + 200-mesh	− 200-mesh

88	0.018	0.12	0.47	0.008	0.026	0.005
136	None	0.053	0.027	0.043	0.011	0.01

quantity along the LaGrange sluice line. The table indicates remarkable horizontal travel of some of the coarse gold and probable lack of economy, from a gold-saving standpoint alone, in maintaining so long a string of boxes. It also indicates that only the more rounded grains of gold finer than 200-mesh are saved and that most of those grains too small to settle in the early boxes do not settle at all.

Capacity. A string of 12-in. Alaskan boxes rarely handles more than 150 cu. yd. per 10 hr., but this is done easily if sufficient water is available. (*100 J 994, 122 P 417.*) Purington (*Bul. 263 USGS 142*) gives the following figures on Alaskan practice: In the South-Coast region a sluice 4 ft. wide × 4 ft. 10 in. deep, slope 0.33 in. per ft., paved with block riffles handled 5000 cu. yd. of gravel and 200,000 cu. yd. of water per 24 hr. Atlin District (B. C.), 400 cu. yd. per 24 hr. of coarse heavy gravel were handled with 32,000 cu. yd. of water in a sluice 24 in. wide, 1400 ft. long, slope 0.5 in. per ft., with block and rail riffles. Klondike bench gravel, 1000 cu. yd. of gravel with 20,000 cu. yd. of water in a sluice 24 in. wide, 20 in. deep, slope 1 in. per ft., block-riffled.

At Y-Water in Australia sluices for treating tin gravels at the rate of 100 cu. yd. per hour are four in parallel, each 10 ft. wide by 3 ft. deep by 180 ft. long. The area of sluices on Australian tin dredges varies from 8 to 43 sq. ft. per cu. yd. treated per hour, all late installations ranging between 30 and the higher figure. The corresponding figure on gold dredges is about 23 sq. ft. in Australian practice and 37.5 sq. ft. in English practice (*16 MM 81*). Purington and Smith (*15 MM 148*) state that a Russian sluice 29 in. wide, 18 in. deep and 280 ft. long, sloped 14 in. in 12 ft., fitted with T-grate riffles and inverted rails set both longitudinally and transversely in different sections, treated 1100 cu. yd. (place measure) per 18 hr. and made 96 per cent. recovery, 88.3 per cent. being made in the first third. *Van Wagenen* gives figures of 100 to 200 cu. yd. of ordinary gravel or 60 to 80 cu. yd. of cemented gravel per man per 10 hr., but this is for sluice-box operators only and does not include delivery of material to the boxes. Hutchins (*Bul. 263 USGS 190*) gives about 5.5 cu. yd. per man shift when shoveling-in and Purington's figures for the same operation range from 2.75 cu. yd. per 10 hr., where large boulders interfered, to as high as 12 cu. yd. with 3-ft. bank and 5-ft. lift.

Use of mercury in sluices is local rather than general custom. It is relatively rare in Alaska and was relatively common in California. This probably followed from the character of the gold, which while perhaps as fine in Alaska deposits as in California, was granular, while the fine California gold was scaly and bright. Hence mercury was considered relatively unnecessary in Alaskan sluices while it was both necessary and highly effective in California. Hutchins (*Bul. 263 USGS 204*) however, brands the failure to use mercury in the Alaska sluices as a penny-wise-pound-foolish policy and recommends its use wherever fine gold that will amalgamate is present. Mercury is commonly used on undercurrents and tables. The finer feed is not so liable to splash it out of the riffles and flour it as the coarse gravel in main sluices and the short length of these devices demands the aid of mercury to keep down the values in the tailing.

Mercury is usually introduced after the riffles have sanded up. It should be put in in such a way as to prevent flouring and in an amount insufficient to flood the riffles. The endeavor should be to maintain as large and as clean a surface of mercury as possible without causing excessive travel along the sluice. In some plants mercury is not introduced until just before the clean-up, in which case its purpose is not so much the recovery of gold as aid in collecting it. A low-grade amalgam (mercury containing a small amount of gold) is more effective than clean mercury.

The quantity used, according to *Bowie*, is about 3 flasks (225 lb.) in the upper 200 to 300 ft. of a 6-ft. sluice. A 24-ft. undercurrent will require 80 to 90 lb.

a Solution 1.35 sp. gr.

Loss of mercury depends principally on the quantity used, the character of the gravel, the type of riffles, and the intervals between clean-ups. *Bowie* gives the loss at La Grange as 0.00024 lb. per cu. yd. He states that at North Bloomfield it was 11 to 25 per cent. of the total used and was greatest in the rock sluices, which were cleaned only at long intervals. At the same mine, with light gravel, low slope and little water the loss was from 4.4 to 6.1 per cent.

12. Coal sluices

Trough washer for coal is a form of sluice that has been used rather extensively in washing bituminous coal at English and Scottish collieries. The simplest form is a trough 1 to 2 feet wide and about three-quarters as deep, 50 to 250 ft. long, set on a slope of 1 in 20 to 1 in 40, with riffle cleats 2 to 4 inches high set at intervals of several feet along the bottom, the number depending on the amount of slate to be removed. Raw coal broken to 1½-in. or smaller is fed at the upper end with sufficient water to move it freely; the slate settles to the bottom and is caught and held in the riffles; the coal flows into a dewatering tank at the end, from which the coarse settlings are removed by a drag chain or bucket elevator while the fine material overflows and is sent to suitable reclaiming devices. When the riffles have filled with slate the flow of feed is stopped and the slate shoveled out. In order to maintain continuous operations, two or more troughs are installed in multiple with a common feed trough, thus allowing one to be cleaned while the other is working.

At Flimby Colliery, Maryport, Cumberland (*11 MIS 184*) two troughs 17 in. wide × 13 in. deep, and 150 ft. long, sloped 1 in 36, with two 2-in. riffles, one near the end, and the other about 20 ft. above, treated 10 tons per hr. with a water consumption of 400 gal. per min. (10 tons of water per ton of raw coal). The velocity of the stream was about 300 ft. per min. The refuse removed was about 18 per cent. of the feed.

Table 5 (*54 IME 455*) shows the results obtained by trough washers treating different sizes of raw coal at three British collieries.

Elliott washer is an improvement on the simple trough washer. It consists of a trapezoidal trough, 50 to 100 ft. long, inclined 1 : 12 to 1 : 18, up the bottom of which full-width flights about 3 in. high travel slowly. These act as riffles and at the same time drag the refuse to the upper end, while cleaned coal discharges at the lower end. Feed is introduced some 20 ft. from the upper end.

A trough 60 ft. long with 12-in. bottom width treats 5 to 10 tons of −1-in. raw coal per hr. with a water consumption of 8 to 10 tons per ton of coal. Table 6 shows performance at a British washery.

Table 6. Performances of Elliott washer. (*After Drakeley*)

a Solution 1.35 sp. gr.

13. Strake

Description. In principle, the strake is a shallow sluice designed for the treatment of fine material. The sluice riffles are replaced by blanket, plush, corduroy, carpet, canvas, silent felt, hides or like material. These serve the same purpose as riffles, but have shallower depressions, which are sufficient to hold concentrate against the wash of the pulp-carrying current but not deep enough to form dams behind which gangue particles collect. The name STRAKE is loosely used, some writers confining it narrowly to cover only blanket-lined machines used in gold milling, but properly the canvas table and all fixed, rectangular machines of the type, using slightly roughened surfaces in lieu of riffles for catching and holding concentrate, should be included.

The WIDTH is usually made that of the blanket or other bottom covering or some multiple thereof; the depth of the sides is merely sufficient to guard against splash, say 3 or 4 in.; the LENGTH depends upon the ore and upon the results demanded but varies in general between 15 and 50 ft. The SLOPE is usually between 1 and 2 in. per ft. and the feed pulp ordinarily carries from 5 to 15 per cent. solids. Pulp is distributed evenly over the width and allowed to flow for a definite time, predetermined by experience and dependent upon the time required for the concentrate layer to build down to the discharge end. The feed is then cut off and, with or without a preliminary washing, the blankets or other bottom covering are lifted out and washed in a tank to remove collected concentrate. They are then returned to the machine and feed is again started.

At PASSAGEM MINE, Brazil (*20 IMM 18*), the ore is gold-bearing quartz containing heavy constituents deleterious in cyanidation. Blanket strakes take −30-mesh stamp product in a pulp containing about 8 per cent. solids. Slope is 1.5 in. per ft. 200 tons of ore per 24 hr. are treated on 400 sq. ft. of blanket and each ton passes over 120 sq. ft. Recovery is about 50 per cent. and the ratio of concentration about 40 to 1. Concentrate assays about 10 oz. Au per ton. Blankets are 48 in. × 18 in. The life of a blanket is 3 weeks. The rough concentrate, amounting to 5 tons per 24 hr., is passed over 12 strakes, 18 in. wide × 20 ft. long, sloped 1.5 in. per ft., the first 8 and the last 4 ft. covered with blankets and the intermediate 8 ft. with canvas. Blankets are washed half-hourly. Concentrate assays about 160 oz. Au per ton and between 650 and 900 lb. per 24 hr. is produced from 5 tons of the rough concentrate. Tailing from this operation assays about 1.3 oz. Au per ton. The concentrate is further treated on two blanket strakes each 18 in. wide and 6 ft. long, producing between 65 and 90 lb. of final concentrate containing 48 to 64 oz. of Au. Tailing assays 16 to 19 oz. Au per ton. This final washing requires about 3 hours and about 16 gal. per min. of water per strake is used.

At OURO PRETO, Brazil (*20 IMM 30*), the ore is gold-bearing quartz containing considerable sulphides deleterious in cyanidation. Blanket strakes treat −30-mesh stamp product in a pulp containing not more than 3 per cent. solids. Slope, 1.5 in. per ft. Blankets are 18 in. wide × 4 ft. long and are changed two to three times per hour, or as soon as the nap becomes loaded with concentrate; 32 blankets can be changed and washed in 10 min. Concentrate assays 8 to 9.6 oz. Au per ton and contains 40 per cent. sulphide. The ratio of concentration is about 40 to 1. The rough concentrate, amounting to about 5 tons per 24 hr., is re-concentrated on 6 strakes each 18 in. wide × 15 ft. long, sloped 1.5 in. per ft. Concentrate assays about 230 oz. Au per ton and tailing about 0.8 oz., all included gold. The ratio of concentration is about 26 to 1. This concentrate is next treated on a table covered with short-nap blanket, 12 ft. long, sloped 2 in. per ft. Concentrate assays 2160 oz. Au per ton and tailing 16 oz.; ratio of concentration 10 to 1. This makes a final overall ratio of concentration of about 10,000 to 1. Water used on the re-concentrating strakes is a weak solution of the extract from the leaf of *Solanum paniculatum*, a local saponin-bearing plant. This solution lowers the surface tension of the water and prevents or lessens flotation of metallic particles.

Planilla is a Mexican device that had its counterpart in China and the East Indies. It consists of a concave sloping surface, a part of which is usally roughened in some way. The apparatus shown in Fig. 20 was built

of masonry and concrete and had a concrete concentrating floor. Brick, wood and sod turned root-side out have also been used for floors, the wood and sod for treating very fine material. The slope and curvature of the surface vary widely.

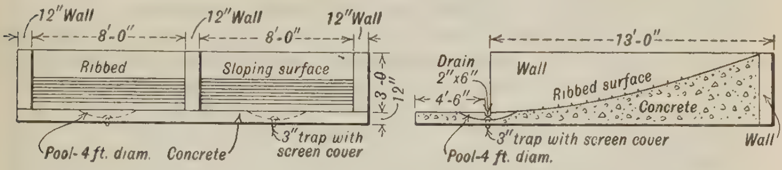

Fig. 20.—Planilla.

Baron (*30 M&M 377*) gives the materials in one planilla such as pictured as 1 bbl. cement, 1000 lb. lime, 5 tons crushed waste and sufficient large rocks for walls and foundations. The labor required was about 5 days for one native mason and two helpers.

Operation. A batch of crushed ore is shoveled onto the higher part, then drawn forward a small amount at a time and washed by throwing water on it or directing a stream against it from a hose. The rough concentrate remaining on the slope after this preliminary washing is turned over and over and coarse material raked up slope while any impoverished surface layers resulting from the turning and washing are carefully scraped off and thrown aside. Concentrate collects in a hard layer beginning at about the point of change of curvature; middling collects below the concentrate and down to the water level; tailing is washed into the sump. Middling is re-cleaned by another washing either with or without further crushing.

Performance. At the San Roberta mine, Zacatecas, Mex. (*30 M&M 377*) a silver ore with lime-silica gangue and small percentages of iron and copper sulphides, crushed and carefully sized through 5-mesh, was concentrated 5 into 1 at the rate of 1 to 2 tons of feed per 9-hr. shift by 1 operator and 2 boys. Concentrate assaying 32 to 40 oz. silver was made from 8-oz. ore and 48- to 60-oz. concentrate from 13-oz. ore, but this was exceptionally good work, obtained by careful sizing of the feed, and close supervision and management. The usual performance on such ore is from 0.5 to 1 ton per shift concentrated 3 or 3.5 into 1 with a recovery of 50 to 60 per cent.

A brick-floored device of the same variety for coarse ore and a board-floored form for cleaning fine middling from the first are described by Collins (*19 IMM 191*) as used in China for treating vein tin ore. Concentrate is re-cleaned in pans.

Film concentration

Concentration by washing on a relatively smooth, sloping surface in a thin film of water is a natural development of the sluice, undercurrent, planilla and strake, applied to treatment of fine material. Building buddles, frames, canvas tables, and revolving round tables represent successive steps in the development. The building buddle dates back to Agricola (1550) and is obsolete in modern plants, but is useful for preliminary work in isolated regions or with primitive labor. The stationary buddle is a useful machine in small, cheap plants. The 20-deck revolving round tables at Anaconda and the multiple-deck tilting slimers in the Missouri lead mills and the southwestern copper plants represent the highest development in film concentrators. These machines have been completely displaced by flotation for the treatment of sulphide ores, but they still are the most efficient devices known for saving extremely fine heavy mineral, not amenable to flotation, from slime pulps.

14. Buddle

The word buddle is limited by some to machines of the variety herein called building buddles; more generally it is made to include all machines for

the concentration of fine sands and slimes in which concentration is effected by flowing a stream of pulp in a relatively thin layer over a substantially smooth, slightly-inclined surface. Thus defined it is distinguished from sluices and undercurrents in which the carrying stream is relatively deep and the separating surface decidedly uneven, and from gold tables and strakes, which have separating surfaces that are intentionally roughened.

Principle of operation of buddles is to utilize the differences in velocity of the different layers in a thin film of liquid flowing over a substantially smooth surface to produce differences in the rate of movement of solid particles of different sizes and specific gravities along the surface. Two kinds of action of the solid particles are involved. The solid particles are more or less in suspension when first fed to the separating surface and they settle according to the laws of free and hindered settling (Sec. 6, Art. 1), the largest and heaviest nearest the feed point, the lightest and smallest farthest down slope or not at all. Friction between the film of flowing liquid and the solid surface, and between the different layers in the flowing film, causes the lowest layer of the film to move at a minimum rate and the upper layer to move at a maximum rate. Since the transporting effect of a current of water varies as a power of the velocity greater than one, the upper layers have the greater transporting effect. This has two results. A particle in suspension in the current is acted upon by a greater force near its upper than near its lower edge, an overturning motion whose resultant is toward the lower layer of the film is imparted, and the settling rate is accelerated. After the particles reach the separating surface, and it is only such particles that can be saved, the current causes them to move down slope by rolling, sliding, or by the movement of alternating suspension and deposition that Gilbert (*Prof. Pap. 86 USGS*) calls "leaping." Rolling and sliding can be considered as due to a substantially non-eddying stream; leaping is caused by eddies. In rolling and sliding, the larger particles, being the ones that project farthest upward from the table surface, are the ones that are acted upon by the most powerful currents, and they move most rapidly, notwithstanding their greater mass. Of two particles of the same size but of different specific gravities, the heavier moves more slowly, under the equal forces applied, by reason of its greater mass. The result, then of the rolling and sliding action of the film on the solid particles in contact with the separating surface, considered alone, is to cause a separation of fine from coarse and heavy from light, the finest heavy material remaining near the upper end and the largest light grains overflowing the lower edge. This is called FILM SIZING. If any of the grains is so large as to stand above the water surface, the transporting force on such a grain, although the maximum that can be exerted by the film, will have less effect than on the larger submerged grains, and such projecting grains will remain near the feed point. When, for any reason, the separating surface is rough, and this necessarily is the case, even on the smoothest bottom, as soon as solid matter begins to settle out, several new effects enter. The depressions in the separating surface act as riffles in which fine particles settle and are protected from the sweep of the current, eddying within the depressions causes concentration of heavy mineral, the rough surface prevents sliding and retards rolling, and eddies are produced in the main stream which sweep smaller particles upward into momentary suspension and cause them to move down slope with a velocity equal to that of larger particles. The net result is to dull the sharpness of the separation of heavy from light mineral.

The flowing stream advances in a series of waves. This fact aids in moving

the larger particles, either because the waves strike definite blows against the larger particles, while failing to strike the smaller, or because, when the crest of a wave is passing, large particles that projected in the trough are submerged.

Davis (*86 J 905*) developed experimentally the following empirical relation between slope (s), in degrees, of a ground-glass surface, water quantity (w) in lb. per min., and diameter in mm. (d) of the average grain of quartz to be washed from a quartz-galena pulp.

$$\sin s = \frac{1}{96}\left(\frac{275 - 50\sqrt{1/d}}{w} + \frac{10}{\sqrt[4]{1/d}}\right)$$

This equation gives no necessary clue to the real relation existing between these quantities and is useful only within the range of the experiments.

Separating surface has an important effect on the performance of a buddle. Truscott (*27 IMM 1*; *28 IMM 46*) believes that this effect is due both to the contour of the surface and the material of which it is made. The depth of the slowest-moving layer in the separating film is less, the smoother the surface, although probably with all surfaces the velocity of the liquid immediately in contact with the surface is zero with respect to that surface. Since any irregularity in the surface produces eddying and the effect of eddying is greatest on the finest particles, it follows that the smoother the surface the better it will hold very fine mineral. (It is not at all unlikely that surface forces, existing at the 3-phase contact between the separating surface, the deposited solid and the liquid, exert some effect, but the hypothesis is not sufficiently established to merit practical consideration.) Rough surfaces catch and hold both gangue and heavy mineral and, if clean concetrate is demanded, such large quantities of water are required to wash out the gangue that much mineral is carried off. Wood, slate, marble, glass, rubber and linoleum have been used to get smooth surfaces and canvas, cement, and fluted glass for roughened surfaces. Data showing the effect of various kinds of surfaces on revolving round tables are given in Art. 19.

Preparation of feed. Considered as film sizing alone, the action of the buddle would seem to demand classified feed and *Richards* so recommends. But as has been shown, the action of a working buddle is never pure film sizing; the part played by the other forces is large, and of such a nature as to defeat separation of classified products. Furthermore on the circular machines (Arts. 16, 18 and 19) the liquid film varies in thickness from center to periphery, and, if made deep enough in its shallowest part to submerge the largest feed particles, will exceed the depth for film sizing in its deepest portion, while if of the right depth in its deepest portion, it will leave the large particles stranded in the shallow areas. Therefore, since true film sizing actually plays but a small part in buddle separation, there is no reason for classified feed. The practical difficulty of classification of the fine sizes usually sent to buddles has also prevented such preparation. It is true that de-sliming a fine sand feed results in better recovery of the granular mineral, but this is due not to better film sizing of the classified material but rather to the fact that removal of the slime decreases the transporting power of the liquid and results in deposition of the fine granular mineral.

Duration of feed is one of the important factors in operation of a buddle. As soon as the stream of feed pulp loses its initial velocity, there is immediate deposition of most of the solid matter. Separation then starts and the solid particles form slowly-moving beds of gangue and mineral progressing toward the discharge lip, with the mineral lagging behind. Feeding must stop before the lower edge of the advancing mineral sheet reaches the discharge. Proper duration depends on the rate of travel of the mineral and the proportion of mineral in the feed. Rate of travel depends on slope, percentage of water in the pulp, feed rate, and retarding character of the surface. When the mineral blanket begins to discharge, there is, on a properly working machine, an immediate rise in assay value of the tailing to that of the feed, the same amount of mineral being added to the impoverished tailing per unit of time, that is abstracted at the upper end.

15. Building buddle

The simplest form is the BOX BUDDLE, a rectangular box, usually with slightly-sloping bottom, the lower or discharge end of adjustable height. Feed is distributed across the upper end by means of a distributor and flows through the box, the lighter material overflowing at the lower end. Solid particles deposit initially in order of size and weight, the heavier and larger particles near

the pulp inlet, ranging gradually to the finest and lightest near the discharge. The slope of the surface of the deposited solids increases to a maximum and with this increase the surface becomes smoother, due to deposition of fine heavy mineral, and the pulp stream becomes thinner. Under these circumstances less and less coarse gangue is able to remain near the head end, but is rolled down slope. When the slope of the settled solids becomes so steep that an excessive amount of concentrate is carried down, the height of overflow is raised, the slope thus lessened, and building again proceeds. If solids build up too rapidly at the head, the feed rate should be increased or feed pulp diluted to increase the velocity of the stream. After the overflow level has been raised to the maximum height feeding is stopped, the bed of solids is marked off into sections representing concentrate, middling, tailing and slime, and the respective sections are shoveled out separately. During the process of building, the surface of the depositing solids should be swept lightly with a cloth or broom to prevent the formation of banks and resulting channeling.

In a building buddle treating a feed containing relatively coarse sands, the action after the bed has begun to deposit is substantially the same as that on a canvas table. With very fine feed the surface of the deposited solids is substantially smooth and concentration takes place largely by film sizing.

Circular building buddles are a development from the foregoing in which the building box is a cylindrical tank usually 18 to 20 ft. diameter and about 18 in. deep with outlet pipes at various levels. A conical feed sole 5 to 6 ft. diameter at the center, and overhead arms revolving 5 to 12 times per min. carrying sweeps of rags or twigs for brushing the building surface, are provided. The products form concentric rings which are shoveled out separately.

Examples

Cornish tin (*24 IMM 422*). Convex pit 14-ft. diameter, with gently-sloping floor; distributing cone, about 5.5 ft. diameter. Overflow is taken through pipes along one element of the cylindrical wall and can be raised 1 in. at a time. Feed is all through 200-mesh. Products of a typical run are: concentrate; 1260 lb. assaying about 25 per cent. black tin; middling, 1420 lb.; tailing, 2870 lb.

Louis states that the capacity of a convex circular building buddle is from 1.5 to 3 cu. ft. of pulp per min., carrying 28 to 56 lb. of solids per cu. ft. Filling requires 3 to 10 hr. and the deposit in the machine is from 6 to 12 tons of solids.

Rumbo (*114 J 672*) is a form of circular building buddle locally developed in the Lenarés district in Spain for treating galena ores. It is a tank 12 ft. diameter and 2 to 3 ft. deep fed at the center with a pulp containing about 33 per cent. solids. Water and slime are worked over the rim by four slow-moving paddles carrying canvas sweeps. It can be filled, stopped and emptied in 5.5 hours and makes a clean concentrate and a tailing containing less than 1 per cent. Pb. Capacity is between 4 and 5 tons of solid per 8 hr.

16. Stationary buddles

These consist of smooth, slightly-inclined stationary surfaces down which finely-ground ore pulp is flowed in a thin film. Heavy mineral deposits near the feed sole, middling down to the discharge edge, and tailing is carried over the discharge edge.

Frame is a film-sizing device consisting of a slightly-inclined smooth-bottomed rectangular trough, open at the lower end to allow free egress of pulp and wash-water streams. The word is loosely but incorrectly applied to rectangular canvas tables and to circular stationary and revolving buddles.

Frames are from 3 to 5 ft. wide, 10 to 20 ft. long, with bottom of smoothly-planed boards, and a slope ranging from 1 in. per ft. for the finest material to 2.5 in. per ft. for fine-sand feeds. It is fed over a distributing board with a thin stream of pulp. Heavy mineral is retarded, as compared to light, and a thin bed of heavy material builds on the separating surface, gradually extend-

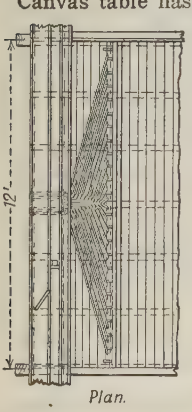
ing to the discharge end. The surface is sometimes worked over with wooden scrapers or brooms to prevent channeling. Just before the advancing sheet of deposited concentrate reaches the discharge end the feed is cut off, the deposit is washed with clean water and caused to discharge a middling product, then the remaining concentrate is removed with a jet of water, or is swept off. By building frames in pairs and providing for diversion of feed pulp to one or the other as desired, and by arranging them to tilt sidewise for washing, considerable time may be saved, one being fed while the other is being washed. Three frames, forming the sides of a triangular prism, mounted on a properly inclined axis, allow practically continuous operation. Water-tilting boxes lever-connected to diverting launders for the products have been used to make the work automatic. None of these devices compares for economy of operation with the revolving round table (Art. 19). The frame is, however, an easily constructed and highly useful slime concentrator for small preliminary plants.

Richards, after extensive experiments (*2 OD 707*; *27 A 76*) recommended a slope of about 0.6 in. per ft. and 12 lb. of water per ft. of width for sandy feed; slope between 1 and 1.25 in. per ft., 5 to 6 lb. of water per ft. of width for fine sand-slime feed; and 1.75 to 2 in. per ft. with 2 lb. of water per ft. of width for the finest slimes. Most writers and millmen, however, recommend a steeper slope as well as a larger water quantity for coarse feeds than for fine.

Capacity, according to *Rittinger*, is about 0.1 to 0.125 ton solid per ft. of width per 24 hr. in a slime pulp containing 8 to 10 per cent. solids and 1 to 1.25 tons per ft. per 24 hr. in a sandy pulp containing 15 to 20 per cent. solids.

Canvas table has been widely used for treating slimes in gold and base-metal concentration. It is better adapted for treating fine feeds than the blanket strake (Art. 13), is usually wider, and the length is less in proportion to the width. Operation is the same as that of the frame. Canvas is not removed for washing concentrate, as is done with the blankets of a strake, but feed is stopped, deposited mineral is washed with a stream of clean water, then swept off with a broom or flushed off with a flat-jet hose.

Wide use was made of canvas tables in California gold mills prior to the adoption of cyanidation, and in base-metal mills prior to the introduction of flotation. At present they are used, under the name of CANVAS FRAMES or RAGGING (ROUGHING) FRAMES in Cornish tin mills and, to a limited extent, supplementing cyanidation in gold mills and flotation in base-metal mills treating complex ores.



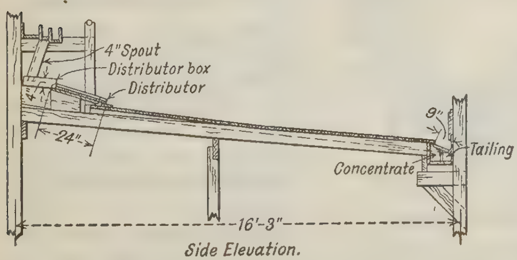


FIG. 21.—Canvas table.

A typical form is shown in Fig. 21. Width varies usually from 3 to 12 ft., length from 10 to 50 ft., slope from 0.5 to 3 in. per ft. Capacity is extremely variable and is dependent on the kind of ore, size of feed, slope, water quantity, and grade of concentrate and tailing demanded; average is about 0.01 to 0.15 ton per sq. ft. per 24 hr. Weight of canvas ranges from 8-oz. to 4-oz. duck. It is usually

stretched lengthwise, for simplicity of construction, although this requires heavier canvas for a given degree of resistance to flow than would be required if the warp of the duck were placed across the stream. The life of canvas is from 8 months to one year under average service, according to the weight used, when protected from the fall of the feed stream by a board, turned when worn too smooth on the upper side, and slipped longitudinally at intervals to bring new places over the joints of the underlying boards. Automatic alternation of feed pulp, wash and flushing water, with automatic throw of the concentrate-tailing splitter has been operated by means of levers from a water-tilting box (see Sec. 21, Art. 10).

At Tul-Mi-Chung (*119 P 808*) canvas tables were used for copper-gold-bismuth ore high in sulphide. The feed was tailing from Deister tables treating flotation tailing (about 0.2-mm. maximum size). Width, 7 ft.; length, 40 ft.; slope 1.25 to 1.75 in. per ft., the former best. One man attended 4 machines. Concrete strakes 4 ft. wide by 50 ft. long on 1.75-in.-per-ft. slope replaced canvas. Concrete was 3 to 6 in. thick tamped level, dressed to slope with a 0.75-in. layer of 1 : 1 cement mortar carefully troweled, which, when nearly dry was dusted with dry cement and scored lightly transversely with a wire comb with teeth at ⅛-in. intervals. Three days were allowed for setting. Twelve of these strakes treated 450 tons solid per 24 hr. (0.13 ton per sq. ft.) in a pulp containing about 12 per cent. solids and recovered about 10 cents in gold per ton treated.

At Suan mill (*119 P 920*) the ore was similar. The feed was tailing from cascade flotation, about 5 per cent. on 100-mesh. 21 strakes, 30 in. wide by 50 ft. long sloped 1 in. per ft., covered with 8-oz. duck, treated 250 to 280 tons solid per 24 hr. (0.11 ton per sq. ft.) and made a low-grade concentrate, but were overfed.

At the Combination mill, Goldfield, Nev. (*94 J 208*), milling gold-quartz ore, canvas tables treated 54 per cent. of the total mill feed and made from 7 to 13 per cent. of the total recovery. Feed contained 85.8 per cent. material through 200-mesh and 93.1 per cent. of the gold recovered came from this size. The cost per ton (1912) was divided as follows: Labor, 18.5¢; repairs, 3.0¢; power, 3.0¢ (including vanners for re-treatment of concentrate); acid for removing calcareous deposit from canvas, 0.5¢; sundry supplies, 5.0¢; total, 30¢.

At Federal Lead Co. in 1913 (*96 J 487*), the feed was galena-limestone ore, slime tailing from vanners, 66 per cent. through 200-mesh, assay 3 per cent. Pb. There were 48 tables, each 11 ft. 8 in. wide, 14 ft. long, slope 1$\frac{9}{16}$ in. per ft., covered with 18-oz. canvas stretched over 2-ply tar paper. The capacity of each table was about 19 to 23 tons solid per 24 hr. (0.14 ton per sq. ft.) in a pulp containing about 19 per cent. solid. One boy washed 36 tables per hr. when making rough concentrate and 24 tables when making clean concentrate. When making rough concentrate at this mill tables were washed every 20 min. Life of canvas was about 8 mo. Efficiency was greater when the canvas was new and fuzzy than later when worn smooth.

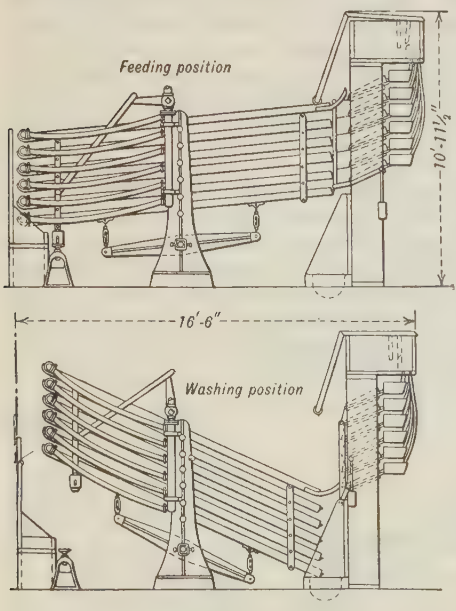

Fig. 22.—Deister tilting slimer.

17. Tilting canvas table

Several forms have been built. The Deister is shown in Fig. 22. It consists of a series of relatively small canvas tables mounted on a tilting framework actuated by a timing device. When in feeding position, pulp is flowed over the canvas decks from the multiple feed box, concentrate adheres to the deck and tailing passes into the tailing launder. After a time predetermined by experiment, the feed is

shut off, the decks tilt into the washing position and flushing water is introduced with sufficient velocity and for sufficient time to remove concentrate, when the decks again tilt to the feed position and feed is again turned on automatically. With a somewhat different mechanism, the BOYLAN (*116 J 766*) and PORTER slimers (*34 MW 453*) accomplish the same result. The feeding period varies from 10 to 30 min. and the washing period from 30 sec. to 1 min. The capacity per square foot of canvas surface is the same as for stationary canvas tables. The WILFLEY multiple-deck tilting slimer (Fig. 23) combines with the multiple tilting deck a simple eccentric shake to aid in stratification of the pulp and a preliminary water-washing period preceding the flushing period, during which wash the worst of the gangue is removed from the deposited concentrate.

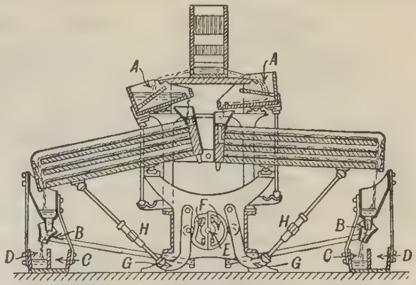

FIG. 23.—Wilfley multiple-deck tilting slimer.

The work of the Wilfley and Deister machines at MIAMI (*115 P 568*) was substantially the same, the machines making recoveries of about 45 per cent. with tailing assaying about 0.9 per cent. Cu from a slime feed assaying from 1.6 to 1.8 per cent Cu. Development of this type of concentrator was practically stopped by the introduction of flotation.

Rotary-tray canvas table is described by Martin (*32 M & M 428*) as having been used successfully in several Mother Lode mills. It consists essentially of a plurality of trays carried on a revolving framework and successively presented to fixed sources of feed and wash water, with final removal of concentrate by a strong, broom-shaped jet. Trays are 4 ft. wide by 3 ft. deep, 21 to 24 trays to a deck and 6 to 10 decks. Speed, one revolution in 15 to 20 min. Canvas, felt and sanded asphaltic paint are used for tray surfacing. Another machine with the same idea has the trays mounted on wheels running on an undulating track which acts to increase the slope of the tray when the discharge position is reached.

18. Circular stationary buddle

In this apparatus (Fig. 24) the separating surface is an obtuse cone, convex or concave, fixed in position, with a central revolving shaft carrying a suitably arranged feed-pulp distributor, wash-water sprays, and diverting launders. In the convex form pictured, fixed launders for concentrate, middling, sand tailing and slime are provided around the outer periphery of the annular concentrating surface. Fig. 25 shows a diagrammatic plan of such a device in operation. The arms carrying the moving parts are assumed to be traveling in a clockwise direction. Feed is introduced from

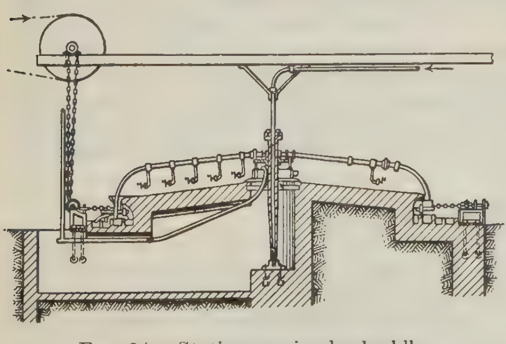

FIG. 24.—Stationary circular buddle.

trough (*a*) extending around one-third to one-half of the inner periphery. The rapidly-moving lighter particles quickly reach the outer periphery, where they are diverted by the movable tailing launder (*b*) to the fixed tailing launder (*c*) and thence to waste. The flowing tailing forms a spirally-bounded patch on the table top as indicated by radial hatching. Under the influence of wash water introduced around the balance of the inner periphery, the slower moving middling next reaches the outer periphery of the table and is diverted by a moving middling launder to fixed middling launder (*e*). The middling forms another spirally-bounded bed, behind the tailing, as marked. Concentrate, traveling most slowly under the influence of the wash water, reaches the outer periphery last and is diverted by the movable launder (*f*) to the fixed launder (*g*). A powerful jet (*h*), carried near the outer periphery and just ahead of the forward end of launder (*b*) removes the last of the concentrate from the path of the advancing tailing area.

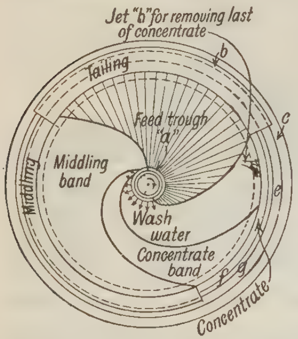

FIG. 25.—Diagrammatic plan of stationary convex buddle.

The concentrating surface is usually wood, iron or cement, but linoleum, glass, and similar surface coverings may be used.

Simons (*46 A 353*) states that these tables are built with as many as 3 decks, 19.5 to 32.75 ft. diameter and that the capacity of the largest size is from 24 to 26.8 tons per 24 hr. per deck. Speed is from 0.25 to 0.43 r.p.m.; power, 0.75 hp.; water consumption 48 to 55 gal. per min. per deck.

An advantage of this type over the revolving round table (Art. 19) is the fact that the heavy concentrating surface is stationary and, therefore, less power is consumed. Also, this surface, once trued remains true, which is not always the case with the revolving tables.

The velocity of the current on a circular convex buddle is greater at the center than at the periphery. This results in deposition of fine gangue near the periphery, but it insures relatively clean concentrate because of the high current velocity near the center, and relatively complete deposition of fine mineral near the periphery. In the concave form, on the other hand, with lowest velocity at the point of initial deposition, much gangue deposits, if substantially complete deposition of heavy mineral is effected. If the velocity at the periphery is made sufficient to prevent deposition of such gangue, fine mineral will be kept in suspension and, with velocity increasing toward the central discharge, never be able to deposit. This is the reason why the concave form has rarely been used.

19. Revolving round table

This is the modern form of buddle. It consists (Fig. 26), of an obtusely-conical surface, substantially smooth, carried on an umbrella-like frame, supported on a vertical shaft resting in a step bearing at the bottom and carrying at the upper end a worm gear by means of which the whole is caused to revolve slowly. A fixed feed distributor supplies pulp to from one-third to three-quarters of the upper surface. Fixed launders around the periphery receive tailing, middling and concentrate. Wash water is supplied over the remaining

surface at the center and there may also be a spirally-disposed spray pipe suspended over the surface along a line such as XX (Fig. 27) that will give a final wash to concentrate before its removal. A strong jet placed just ahead of the tailing launder insures removal of the last of the concentrate. In Fig. 27, consider three particles of the same size but different weights, say concentrate, middling and tailing respectively, starting at point (a). The motion of each with respect to the table surface is radial in direction, but the velocities will vary inversely as some function of the specific gravities. After a short interval of time, therefore, the radial components of travel will be as indicated by the vectors (c), (m) and (t), respectively. The angular travel will be the same for all three, say to the position of radius (r_1); the resulting positions will be (c_1), (m_1) and (t_1), respectively, and the paths the dotted spirals connecting (a) with the respective points. After a second increment of time during which the original radius has moved to the position (r_2), and during which also the radial travel of the particles will be less than in the preceding interval by reason of the lessened velocity of the pulp stream due to its increasing width and decreasing depth, the tailing particle will have left the table at position (t_f), while middling and concentrate particles will be at (m_2) and (c_2) respectively. They will finally leave the table at positions (m_f) and (c_f). Differences in rate of radial travel will be greater, if the concentrate and middling particles are smaller than the tailing particle.

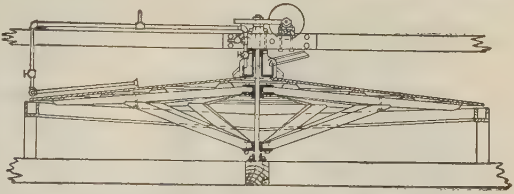

Fig. 26.—Revolving round table (single-deck).

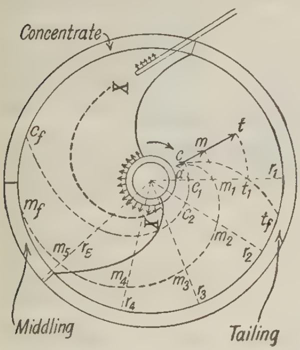

Fig. 27.—Sketch of action of revolving round table.

Evans revolving round table was furnished with a fixed conical center head with spiral periphery, so arranged that concentrate depositing on the upper portion of the table in the feed sector would pass under the head and be protected from further washing by feed pulp, but would be exposed when the wash sector was reached. This type of table has been extensively used in Lake Superior copper mills and in the early days at Anaconda.

Multiple-deck revolving round tables (Fig. 28) were devised to overcome the handicap of low capacity. The limit was reached in the 20-deck Anaconda table shown. The decks were 19 ft. diameter, built of concrete laid on sheet-steel support spaced 1 ft. apart vertically. The 20 decks were carried on eight steel columns around the outer periphery and the columns rested on a steel ring running on wheels on a circular track. Motion was transmitted through a pinion to a circular rack carried on the lower side of the supporting ring. A central shaft-way, 4 ft. in diameter, carried the distributing pipes for pulp and wash water and enclosed a 30-in. square ladderway.

Extensive tests were carried out at ANACONDA preceding the construction of the round-table plant (1912). The reports of these tests by Crowfoot (*49 A 417*) and Laist and Wiggin (*49 A 470*) are substantially a text book on the subject and form the principal basis for the following paragraphs.

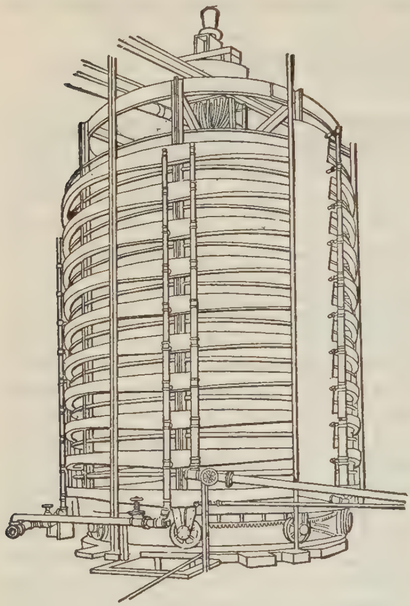

FIG. 28.—Multiple-deck revolving round table.

Surface. Planed wood, linoleum, medium-weight canvas and cement concrete were tested. The concrete mixture was one cement and two sand, laid on sheet steel, trowled to a finish approximating that of the medium-weight canvas. (At OHIO COPPER Co. concrete 2 in. thick was laid on reinforced expanded metal (*90 J 1107*)). Results are given in Tables 7 and 8. Slightly higher recovery was made on the wood than on the cement; the greater tonnage of tailing rejected by the cement deck is a distinct advantage in its favor. The canvas deck made a distinctly higher recovery than the cement, but the grade of tailing was the same and the grade of concentrate markedly better on the cement deck; it also had better wearing quality.

Comparison between cement decks with rough and smooth finish is shown in Table 9. The smooth-finished deck made somewhat better recovery with lower water consumption on the high and low tonnages, but the concentrate was lower grade. On medium tonnage, recovery, tailing and grade of concentrate were all better on the rough-finished tables, although water consumption was markedly higher.

Table 7. Comparison of wood, linoleum and cement deck surfaces on revolving round tables at Anaconda Copper Co.

	Kind of deck		
	Wood	Linoleum	Cement
Tons solid per 24 hr.	4.4	4.5	4.5
Per cent. solids in feed	7.6	7.5	7.5
Assay of feed, per cent. Cu	2.77	2.75	2.76
Assay of concentrate, per cent. Cu	5.29	5.92	7.03
Assay of tailing, per cent. Cu	1.55	1.65	1.61
Recovery, per cent.	62.1	55.3	53.8*a*
Ratio of concentration	3.1	3.9	4.7
Water, fresh, gallons per ton of feed	6022	4974	5424

a Results on cement decks were greatly improved in later work. See Table 9.

When using rough-surfaced cement and canvas-covered decks, solids built up as much as ⅜ in. deep. Yet the tests just described show that notwithstanding the building, the rough deck affords better protection for sulphide and holds it back against the wash-water.

Fluted- and corrugated-glass surfaces have been tested against wood on revolving round tables in the CORNISH TIN MINES (*14 MM 32, 89, 90, 154, 333*). Various forms of glass surface have been tried, but the best results were obtained with about 16 flutes to the inch,

1⁄32 to 1⁄16 in. deep, with crests either sharp or rounded. In one 16-hr. test on an 18-ft. glass-top, concave table with corrugations set at right angles to the slope, slope 1.5 in. per ft., when running against a wooden deck of the same diameter sloped 1.25 in. per ft., the glass top yielded 847 lb. of concentrate assaying 32.2 lb. Sn per ton and the wood 1557 lb. of 15-lb. concentrate. The tailing on both decks carried 6.5 lb. Sn per ton and the feed 9.2 lb. Sn per ton. The feed rate on the glass deck was 5.7 tons per 24 hr.; on the wood, 3.8 tons. The glass deck worked under the disadvantage that the deck was pyramidal rather than conical so that there was a rush of pulp in the valleys at the joints. Tailing assay at the center of a glass section was 5 lb. Sn per ton against 7.5 lb. at the joint. Trewartha-James (*14 MM 89*) says that the glass top is very sensitive to variations in size, pulp density and mineral content and that the pulp density must be closely correlated to the slope. The glass top is said to be better than the wood on rounded particles.

Table 8. Comparison of cement and canvas deck surfaces on revolving round tables at Anaconda Copper Co.

	Kind of deck	
	Cement	Canvas
Tons solid per 24 hr.	8.3	8.3
Per cent. solids in feed	9.3	9.8
Assay of feed, per cent. Cu	3.36	3.46
Assay of concentrate, per cent. Cu	7.84	5.79
Assay of tailing, per cent. Cu	0.93	0.94
Recovery	82.0	87.0
Ratio of concentration	2.9	1.9
Speed, minutes per revolution	19	19
Slope of deck, inches per foot	1.2	1.13
Water, fresh, gallons per ton of feed	1218	1517

Note—Crowfoot states that the extra cost of handling, transportation and smelting of the lower-grade canvas-deck concentrate would probably more than offset the increased recovery.

Table 9. Comparison between rough-finish and smooth-finish cement-deck round tables at Anaconda

Character of feed	Rough finish			Smooth finish		
	Medium	Fine	Fine	Medium	Fine	Fine
Tons solid per 24 hr.	31.5	12.3	4.8	20.2	14.0	6.3
Per cent. solids in feed	16.5	9.0	7.1	11.9	7.1	7.7
Assay of feed, per cent. Cu	4.25	3.37	4.23	4.86	3.23	2.63
Assay of concentrate, per cent. Cu	18.90	16.64	19.06	17.00	16.08	13.90
Assay of tailing, per cent. Cu	2.21	1.47	1.82	2.34	1.51	1.01
Recovery, per cent.	54.0	62.1	63.0	60.5	58.8	66.6
Ratio of concentration	8.2	8.0	7.2	5.8	8.4	8.0
Water, dressing, gallons per ton of feed	440	2035	3746	651	1424	3378
Water, concentrate removal, gallons per ton of feed	814	2480	6078	1094	1171	2491
Water in feed, pounds per minute per foot of total circumference	4.15	2.88	1.70	3.88	4.74	1.95
Water, dressing, pounds per minute per foot of total circumference	1.39	2.60	1.82	1.34	2.15	2.11
Water, concentrate removal, pounds per minute per foot of total circumference	2.86	3.32	3.18	2.40	1.79	1.69
Speed, r.p.hr.	2	2	2	2	2	2

Contour of surface. The length of the cross-section of the pulp or wash-water stream on a convex round table, cut along a line equidistant at all points from the center of the table, increases, obviously, as the distance from the center to the chosen section increases. Since the volume of water flowing down any given sector is substantially constant for any given position of the sector, the thickness of the film must necessarily decrease as the periphery is approached. This results in a decrease in velocity with resultant deposition of solid matter, principally gangue. Professor H. S. Munroe (School of Mines, Columbia Univ.) proposed a convex conoidal deck, to increase the water velocity near the periphery and thus

prevent deposition. Table 10 presents comparative performances of the conoidal and conical decks. The conoidal deck with chord sloping 1 in. per ft. substantially duplicated the performance of the conical deck sloping 1.25 in. per ft. With steeper slopes the conoidal deck made a higher grade of concentrate but lower recovery. The conoidal deck of a given slope required a thicker feed pulp than the conical deck and less wash water.

Table 10. Comparison of performances of conoidal (*b*) and conical (*c*) cement decks on revolving round tables at Anaconda

Contour of deck	Conoidal			Conical
Slope, inches per foot(*a*)	1.25	1.125	1.00	1.25
Tons of solid feed per 24 hr	6.5	6.9	6.9	7.0
Per cent. of solids in feed	9.9	9.9	9.9	9.8
Assay of feed, per cent. Cu	2.67	2.66	2.46	2.37
Assay of concentrate, per cent. Cu	12.15	8.89	5.92	5.92
Assay of tailing, per cent. Cu	1.11	0.97	0.94	0.87
Recovery, per cent	64.2	71.4	73.5	74.1
Ratio of concentration	7.1	4.7	3.3	3.4
Water, fresh, gallons per ton of feed	2659	2535	2711	2967

a On conoidal deck this is slope of chord of arc. *b* Diameter, 17 ft.; working radial length, 7 ft. 3 in.; speed, 1 revolution in 20.5 min. *c* Diameter, 18 ft.; working radial length, 7 ft. 9 in.; speed, 1 revolution in 16 min.

Cost of a conoidal cement deck on a 17-ft. table was as follows: Sand, 2890 lb. @ 17¢ per ton, \$0.25; cement, 14 sacks (@ 93 lb. per sack = 1302 lb.) @ 70¢ per sack, 9.80; labor, 4 man-days @ \$3.25, \$13.00; haulage, \$2.00; total, \$25.05.

On any given sector in position for concentrate removal the solid near the apex of the sector was coarser and richer than that near the rim, which shows the action of the round deck as a whole is not true film sizing but rather progressive deposition of the heaviest particles as the velocity decreases toward the rim after which film sizing removes the larger gangue particles. The deposit along the upper part of the slope was as high grade as could be made by re-treating the whole concentrate from the revolving tables on shaking tables, therefore the spray water was arranged so that the peripheral concentrate was first washed off as middling for further concentration and the rich upper streak was removed separately as finished concentrate.

Slope affects recovery, grade of concentrate and capacity. It is interdependent with quantity of wash water, a flat slope requiring more water to produce a given grade of concentrate than steep slope. On the other hand steep slope tends to lower recovery. Capacity is greater with steep slope.

The Anaconda tests showed that a slope of 1.25 in. per ft., for conical cement decks, was best for treating slimes containing 4 to 5 per cent. on 200-mesh. At less than 1.125 in. per ft. excessive gangue deposited while with more than 1.375 in. per ft. tailing loss was excessive. Linoleum decks also gave best results at 1.25 in. per ft. The best slope for the conoidal deck was 1.125 in. per ft. measured along the chord of the arc. Standard practice in Lake Superior copper mills is 1.5 in. per ft. with occasionally as low as 1.25 in. per ft. in treating very fine material. Anaconda tried a 2-slope convex-conical table with the central 5 ft. sloped 1 in. per ft. and the peripheral 30-in. sloped 1.25 in. per ft. and 1.25 in. drop at the line of change, but results were no better than on the conical deck with 1.25-in. slope.

Speed determines the horizontal component of velocity of particles and, therefore, fixes the radial velocity required to discharge products at the proper places on the periphery. High speed of revolution requires steep slope and much wash water; low speed, *vice versa*. In Lake Superior copper mills the speed on relatively coarse sandy feeds is 1 rev. per min. In some of the slime-testing work at Anaconda 1 rev. per 100 min. was tried, but channeling occurred. Increase to 1 rev. in 19 min. eliminated channeling. One rev. in 4 min. was the speed for the 20-deck machines when run to make finished concentrate and tailing and a circulating middling. At Ohio Copper Co. the speed of 20-ft. machines was 1 rev. in 72 sec.

Diameter affects the length of separating surface parallel to the flow of material and determines the allowable duration of feed. With small diameter the time required for the sheet of concentrate to travel from feed to tailing-discharge point is relatively short and duration of feed to a given section must be made correspondingly short by increasing speed of revolution. Greater diameter or less slope permits lower speed.

Feed. Early practice was to send a sandy feed, say all through 0.3-mm., to round

tables, either removing slime ahead of the table or counting on the table to make some small saving from it, discarding the bulk. Shaking tables largely displaced the round table in sand treatment because of greater capacity, higher recovery, ability to make finished tailing and concentrate at one operation and ability to separate sand from slime. The round table was then applied only to slime treatment. It makes cleaner concentrate when sand is eliminated than otherwise. Anaconda tests on concentrate showed that the part held on a 200-mesh screen assayed but 1.35 per cent. Cu while the undersize assayed 6.95 per cent. On the other hand, the presence of semi-colloidal matter in the feed causes sulphide to be carried into the tailing.

With slime feed the best pulp consistency at Anaconda was between 8 and 12 per cent. solids. Thicker pulp was so viscous that separation was difficult while thinner pulp had to be fed so slowly that capacity was unduly reduced. Pulp consistency had little effect on recovery at Ohio Copper Co. (*90 J 1107*).

For roughing, the feed can be introduced over all of the surface except a small sector devoted to removing concentrate. When clean concentrate is desired, feed is distributed on one-half to three-quarters of the total surface. On the 20-deck Anaconda tables the feed was run onto 70 per cent. of the deck, dressing water on 18 per cent. and 12 per cent. was devoted to concentrate removal.

Water consumption depends upon the size of feed particles, grade of concentrate desired and slope and character of deck surface. Water is supplied with the feed, as dressing water at or near the center, and as spray water for concentrate removal near the periphery. The 20-deck, cement-surface tables at Anaconda, treating 6 to 7 tons solid feed per deck per 24 hrs., required 3 gal. dressing water and 6 gal. spray water per min. The feed pulp contained 10 to 15 per cent. solids. Coarse feed requires the most water; more water is required to make high-grade concentrate than for low-grade. Canvas decks require more water than cement. Linoleum decks require less water than cement; wood require more. Conoidal decks require less water than conical. Richards (*TB 377*) gives the average water discharged per ft. at the periphery of 18-ft. tables in Lake Superior mills as 31.8 gal. per min. pulp water; 10.6, dressing water; and 9.5 spray water.

Power consumption is about 0.15 to 0.25 hp. per deck for tables 15- to 18-ft. diameter, the lower figure applying to the multiple-deck tables. The 20-deck tables at Anaconda each had a 5-hp. motor and actually consumed about 3 hp.

Attendance required is low, especially if the feed is regular. At Anaconda each operator took care of four 20-deck tables.

Capacity depends largely on the size of feed and slope of deck, being higher for relatively coarse feeds and steep slopes. At Lake Superior mills 10 to 20 tons of relatively sandy feed are treated per deck per 24 hr., the decks ranging from 16 to 20 ft. diameter. Final figures on Anaconda slimes were 6 to 7 tons per 24 hr. per 19-ft. deck or about 45 sq. ft. of deck area per ton of total feed, including 8 to 10 per cent. returned middling. At Ohio Copper Co. a 20-ft. deck treated 12 tons dry slime per 24 hr. and could treat 15 tons without crowding, making, however, only 20 per cent. recovery as against 54 per cent. at Anaconda.

Recovery. Probably 40 to 50 per cent. is the average range of recovery on slime feed. Some Lake Superior recoveries have run as high as 80 per cent., making a low-grade concentrate. The average of all Anaconda experimental work showed 54 per cent. net recovery of silver and copper in a concentrate assaying about 6.5 per cent. Cu from a slime feed assaying 2.25 per cent. Cu. Operation of 20-deck tables in April, 1913, yielded 51.6 per cent. recovery in the form of a concentrate assaying 7.02 per cent. Cu from a 1.95-per cent. feed. Tailing assayed 1.13 per cent. Cu.

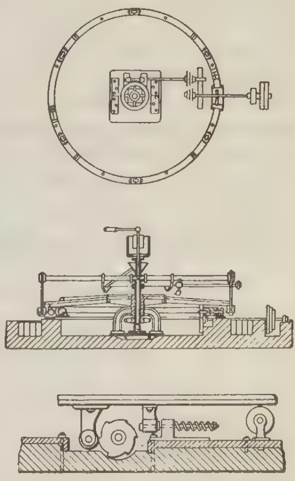

Fig. 29.—Bartsch round table.

Bartsch round table (Fig. 29) is a substantially convex stationary circular buddle with a differential tangential bump applied to the separating deck. Diameter is 13 ft.; speed of spindle, about 0.5 r.p.m.; 100 to 120 @ ⅜- to ¾-in. strokes per min.; power consumption, 0.25 to 0.5 hp.; water consumption, 12 to 35 gal. per min. according to the specific gravity of the gangue. (*46 A 358.*)

SECTION 9

JIGGING

Jigs are mechanical concentrators that utilize the differences in falling rate of grains of different specific gravities and sizes, in a semi-fluid mass of solid particles suspended in water, in order to effect separation of the heavy from the light. The maximum practical feed-size for heavy ores is about 1.5-in.; 3-in. material has been handled, but not very satisfactorily. The average upper size limit at the present time is about 0.5-in. and the minimum about 1-mm. (0.04-in.), but for sizes below 2-mm. (0.08-in.) shaking tables (see Sec. 10) are better machines. The maximum feed size in coal treatment is 4½-in., minimum ⅛-in.

Jigs consist essentially of a screen which supports an ore bed that is brought into partial suspension at regularly recurrent intervals by means equivalent to a current of water forced upward through the screen. Following suspension the bed comes again to rest on the screen, either by settlement under the action of gravity alone or aided by subsidence of the water. The water currents are brought about either by moving the sieve in a tank of water (MOVABLE-SIEVE JIGS) or by moving water through a fixed sieve (FIXED-SIEVE JIGS). After a few repetitions of the pulsation-subsidence cycle, distinct stratification of the ore particles on the screen is effected, grading from heaviest at the bottom to the lightest at the top, and, if the screen apertures are large enough with respect to the particles treated, with the small heavy particles in the tank below the screen. Final separation of the material on the screen is effected by skimming off the surface layers and collecting the lowest layer, either manually or automatically by means of suitable contrivances.

1. Principles of jigging

Separation of heavy from light particles takes place during both of the oppositely-directed motions occurring in each cycle of the jig movement, due to difference in rising rate of the particles under the upward impulse of the water currents and difference in falling rate in the still or downward-moving water during the remainder of the jig cycle. During the upward movement particles of heavy mineral of a given size lag behind particles of light mineral of the same size, both because the heavy mineral is slower to start on account of its greater inertia and because its terminal velocity under a given upward impulse is less than that of the light. (See Sec. 6, Art. 1.) During this same part of the cycle all small particles rise faster and farther than

their larger companions because their inertia is less, their falling rate less and their smaller size permits them to be freed more quickly from the interlocking effect of the settled bed. In their own size class, however, the tendency toward vertical separation is the same as that of the larger particles and the heavier lag behind. At the end of the upward movement the largest heavy particle in the mass has been lifted the least distance, the largest light-weight particle has been lifted a greater distance and the same distance as some smaller heavy particle; while the smallest particle of light mineral has been lifted farthest. When the upward impulse, called PULSION, ceases, it is succeeded by a period during which the suspended solid particles settle back into a mass on the screen. If this settlement is accompanied by downward movement of the water, the jig is said to be running with SUCTION; otherwise it is said to be running with pulsion only. At the beginning of the settlement period the heavy particles settle most rapidly because the settling rate during acceleration depends on specific gravity only. After constant velocities are reached, if there is time in the jig cycle for establishment of such a condition, the heavy particles of any given size settle more rapidly than the light particles of the same size and, so long as either free- or hindered-settling conditions obtain, there is equal settlement of particles of heavy and light mineral having diametral ratios in accord with the equation $d_L/d_H = (\delta_H - \delta')/(\delta_L - \delta')$ in which d_L and d_H are the diameters of light and heavy particles respectively, δ_L and δ_H are corresponding specific gravities, and δ' is the specific gravity of the suspending fluid, being 1.0 for free-settling and, in hindered-settling, the specific gravity of the bed itself in a quicksand state. But experience shows that particles of heavy mineral very much smaller than would be expected from the above equation can be separated from light particles of a given size on a jig bed. This is due to the fact that when the bed compacts to an extent that the quicksand conditions of hindered-settling no longer exist, the large particles of light mineral are interlocked and can no longer move downward, while small particles are still free to move down through the interstices between the larger and do so. This downward movement of the small particles is increased by suction, it may be to the extent that fine particles of light mineral are likewise drawn through the bed and screen.

Simons (*68 A 431*) develops mathematically equations that represent the facts during the time that the bed is loose enough to prevent interlocking of the grains, but his work does not include consideration of the interstitial movement of fine particles.

Starting with the fundamental equation $h = \frac{1}{2}gt^2$, where h = distance of fall due to gravity, g = acceleration due to gravity and t = time, he shows that for the first moments of fall in still water this equation becomes substantially $h = \frac{1}{2}g_1t^2$ where g_1 = acceleration in water. His assumption is that since the resistance of the water to the particle varies with the square of the velocity of the particle, the initial resistance, during the period of low particle velocity, is relatively small and can be neglected and that acceleration during this time will, therefore, be constant. From this it follows that the falling height,

$$h = \frac{gt^2}{2\delta}(\delta - 1), \qquad (1)$$

where δ = the specific gravity of the falling particle. Indicating particles of light and heavy minerals by the subscripts 1 and 2 respectively

$$h_2 - h_1 = \frac{1}{2}gt^2\left[\frac{1 - \frac{\delta_1}{\delta_2}}{\delta_1}\right], \qquad (2)$$

from which it appears that at the beginning of fall, which is the time that must be considered in a jig using short, rapid strokes, the ease of separation, measured by $h_2 - h_1$, increases with difference in density of the particles and that the size of the particles does not enter. From this same equation it follows that, with the same ratio $\frac{\delta_1}{\delta_2}$, ease of separation increases with decrease in the absolute values of δ_1 and δ_2.

For any pair of equal-falling particles whose diameters are d_1 (light) and d_2 (heavy) respectively, settling in still water, it follows from equation (1) that the respective falling heights during the first moments of fall are

$$h_1 = \tfrac{1}{2}gt^2\left[\frac{d_1(\delta_1 - 1)}{d_1\delta_1}\right],$$

and

$$h_2 = \tfrac{1}{2}gt^2\left[\frac{d_2(\delta_2 - 1)}{d_2\delta_2}\right].$$

From the equal-falling postulate

$$d_1(\delta_1 - 1) = d_2(\delta_2 - 1) \qquad (3)$$

and therefore

$$h_1d_1\delta_1 = h_2d_2\delta_2. \qquad (4)$$

From equation (3) it follows that $d_1 > d_2$. Hence $d_1 + d_1(\delta_1 - 1) > d_2 + d_2(\delta_2 - 1)$ and $d_1\delta_1 > d_2\delta_2$, therefore, $h_2 > h_1$. This means that of two particles equal-falling under free-settling conditions, the more dense falls farther in the first moments of fall.

The distance through which a spherical particle will fall in the first moments in a downward current of velocity, v_d, is

$$h = \tfrac{1}{2}gt^2\left[1 + \frac{3cv^2_d - 4gd}{4gd\delta}\right], \qquad (5)$$

c being an empirical coefficient. From this equation it appears that h depends on the relation between $3cv^2_d$ and $4gd$. If subscripts 1 and 2 represent particles of unequal density, 2 being more dense, then, for particles of equal size

$$h_2 - h_1 = \frac{t^2(\delta_2 - \delta_1)}{8d\delta_1\delta_2}(4gd - 3cv^2_d). \qquad (6)$$

The difference is a maximum when $v_d = 0$, which means that jigging of equal-sized particles is most readily performed with no suction.

When the particles are of the same density but different sizes, subscripts 1 and 2 referring to the smaller and larger particles respectively,

$$h_2 - h_1 = \frac{3cv^2_d t^2}{8\delta}\left(\frac{d_1 - d_2}{d_1d_2}\right), \qquad (7)$$

and $h_2 - h_1 = 0$ when $v_d = 0$. This indicates that there is no difference in the rate of fall of different-sized particles of the same density in the first moments of fall in still water. If there is any downward velocity of the water, $h_2 - h_1$ is negative, showing that the smaller particle falls more rapidly at first. When particles are equal-falling under free-settling conditions, the falling heights h_1 and h_2 of light and heavy particles respectively during the first moments of fall are given by the equations:

$$h_1 = \tfrac{1}{2}gt^2\left(\frac{d_1(\delta_1 - 1)}{d_1\delta_1} + \frac{3cv^2_d}{4gd_1\delta_1}\right), \qquad (8)$$

$$h_2 = \tfrac{1}{2}gt^2\left(\frac{d_2(\delta_2 - 1)}{d_2\delta_2} + \frac{3cv^2_d}{4gd_2\delta_2}\right). \qquad (9)$$

Under the conditions postulated

$$d_1(\delta_1 - 1) = d_2(\delta_2 - 1).$$

Multiplying both sides of equations (8) and (9) by $d_1\delta_1$ and $d_2\delta_2$ respectively, it appears that

$$h_1d_1\delta_1 = h_2d_2\delta_2.$$

Under the hypothesis $\delta_1 < \delta_2$, hence $d_1 > d_2$. By the method of proof followed in discussing equation (4), $d_1\delta_1 > d_2\delta_2$ and therefore $h_2 > h_1$. This indicates that with suction and rapid short strokes, separation by jigging can be effected between equal-settling particles obtained by hydraulic classification.

Rittinger, reasoning on the assumption that jigging is a free-settling phenomenon (see Sec. 6, Art. 1), set up the rule that the ratio of the diameter of the largest light grain to that of the smallest heavy grain that should be jigged with it should not exceed that given by the equation $d_L/d_H = (\delta_H - 1)/(\delta_L - 1)$ and continental jigging practice followed this rule closely.

Munroe (*17 A 637*) investigated American practice and concluded that its success in saving heavy particles much smaller than Rittinger's rule indicated was attributable to the fact that free-settling conditions exist for a very small part only of the jig cycle, if at all, and that during the greater part of the cycle the effective phenomenon is movement of water currents in the irregular passages existing in the bed of relatively quiescent coarse particles settled and supported in substantial contact on the jig sieve.

By experiments with spheres of different sizes falling in circular tubes Munroe developed the equation

$$V = K\left[1 - \left(\frac{d}{D}\right)^{\frac{3}{2}}\right]\sqrt{d(\delta - 1)} \qquad (10)$$

in which V is the velocity, following the period of acceleration, of a sphere whose diameter is d and specific gravity δ falling in water in a tube whose diameter is D. K is an empirical coefficient equal to 5.11 when d and D are taken in meters and V in meters per second. When the diameter of the sphere is less than one-tenth the diameter of the tube, its falling velocity is but little affected by the walls, but when d approaches D the falling velocity is much reduced. Maximum falling velocity in a given tube is attained by a sphere whose diameter is four-tenths that of the tube. Experiments with a mass of shot supported on a screen in a tube showed that these obeyed the same law as is expressed in equation (10), but that the falling velocity of the mass of spheres (*i.e.*, the velocity of the current required to just lift them) is less than one-sixth that for a single isolated sphere of the same material. For the mass of shot the average value of d/D determined by substituting observed experimental values for V in equation (10) was 0.892 and substituting this value in equation (10) reduces it to

$$V = 0.833\sqrt{d(\delta - 1)}. \qquad (11)$$

Similar experimental work established the equation

$$V = 0.307\sqrt{d(\delta - 1)}, \qquad (12)$$

as governing the fall of a large sphere when surrounded by a mass of much smaller spheres.

In the bed of a jig treating a mixture of large light and small heavy particles the large light particles will obey equation (12) and the small heavy particles, equation (11). The limiting case for separation exists when

$$V_H = 0.833\sqrt{d_H(\delta_H - 1)} = V_L = 0.307\sqrt{d_L(\delta_L - 1)},$$

from which $d_L/d_H = 30$ for galena and quartz. This compares with the ratio $d_L/d_H = 4$ under free-settling conditions. In a jig bed in which the interstitial channels were 1 mm. average diameter, the diameter of the most rapidly-moving quartz grain would be 0.4 mm. From equation (10), a 0.015-mm. grain of galena would have the same velocity. According to Munroe's assumption, the largest grain of quartz that can move in these channels is 0.89 mm., from which it would appear that with such fine material a ratio of $d_L/d_H = 0.89/0.015 = 60$ was allowable. Munroe further concludes that for fine jigging it is necessary to have this interstitial action and that it can be obtained only by the presence of larger material on the bed.

Richards (*24 A 409*) tested Munroe's work on interstitial currents by sorting tests in a hindered-settling glass classifier and concluded that while interstitial currents were effective in jigging, the ratio of diameters of quartz and galena particles that could be effectively treated together was 6, not 30 as determined by Munroe. The practical test of operations is, however, on Munroe's side.

Effect of suction. Tables 1 and 2 show: (1) The rapidity with which a separation by jigging can be made is greater the larger the differences in the specific gravities of the mater-

ials jigged. (2) In jigging closely-sized feed, suction should be reduced to a minimum. This is particularly so when the difference in specific gravity is great. (3) Jigging without suction fails when the ratio of diameters of light to heavy mineral exceeds the free-settling ratio. (4) In jigging a feed in which the ratio of particle diameters exceeds the free-settling ratio the necessity fo strong suction is greatest when the difference in specific gravity is least. (5) The galena tests (Table 1) indicate that heavy-mineral particles which are nearly equal-settling with the largest quartz are particularly slow-settling with heavy suction, due, probably to the fact that they get little advantage in free-settling and are too large to get through the interstices during the suction period. The same phenomenon is shown in Fig. 1 (*95 J 785*). (6) The great changes in rapidity that occur in the heavy-suction tests in both series between the sizes

0.67- and 0.50-mm. indicate that the average diameter of interstitial passages in 1.73-mm. quartz lies in this range.

Capacity of jigs is almost entirely proportional to the transporting effect of the horizontal current and to the fluidity of the bed. The more fluid the bed, the greater the transporting effect of a given horizontal current. The limiting requirement is that the finest material that is to be saved shall settle and have a chance to pass down into the bed. The cross current must not be so great that the bed is churned up. Transportive effect is increased by increase in volume of cross water and by the increase in velocity gained by increasing the drop between screens. The latter is the better method because it saves water and lessens the danger of carrying valuable material in suspension. Increasing the plunger stroke or the quantity of hutch water increases the fluidity of bed. Long plunger stroke is not allowable on fine jigs because it produces boiling. Capacity is proportional to sieve area; it increases with increase in width but increase in length has not so great an effect. The usual range on heavy ores is from 0.5 to 2 tons per 24 hr. per sq. ft. of sieve area in fixed-sieve jigs and 4 to 9.5 in the movable-sieve type.

FIXED-SIEVE JIGS

2. Harz jig

Description. The Harz jig is shown in Fig. 2. It consists usually of a plurality of separate and independent rectangular hopper-shaped compartments, with the upper part subdivided by a shallow central partition into a screen compartment and a plunger compartment. The screen is fastened to grate (*K*), which is held in place on the lower, fixed liners by upper liners that are held in by wedges. Reciprocation of the plunger causes flow of water through the screen. Feed enters the first screen compartment through slot (*b*). The longest plunger stroke and consequently the most rapid pulsation are maintained in this compartment. The heaviest particles settle to the screen, the finer particles pass through into the lower part of the compartment, called the HUTCH; the coarse heavy particles collect on the screen until a bed is formed, when they pass under hood (*F*) and over the lip into spout (*J*); light material passes over tail-board (*C*) into the second compartment, where it is subjected to currents of lower velocity by means of which the heavier part of the remaining material is removed and the lighter goes on into the third compartment, etc.

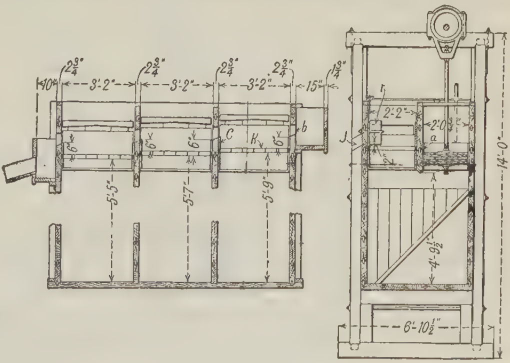

FIG. 2.—Harz jig.

Design of Harz jig. The important points are: size and number of screen compartments, drop between screens, length and number of plunger strokes, size and placing of concentrate draw, sizes of timbers, height of tail-

board, depth of longitudinal partition, design of plunger, kind of screen and grate, ease of changing screen and kind of hutch gate.

Number of compartments depends upon the duty demanded and upon the size of material treated. If the jig is required to make one finished concentrate only, a single-compartment jig will do the work. If two concentrates of different minerals are to be taken but finished tailing is not desired, a 3-compartment jig is required, making clean heavy mineral on the first compartment, clean mineral of intermediate specific gravity on the third, a middling product consisting principally of locked grains of the heavy and intermediate-weight mineral in the second, and a product over the tail board of the third compartment containing little or no free mineral but much middling. If clean tailing is likewise desired, from three to nine compartments will be necessary, depending upon whether one or two concentrates are to be taken and also upon the relative specific gravities of the gangue and valuable minerals, as well as upon the grade of tailing desired. For a one-mineral separation such as quartz-galena, three compartments will serve, if tailing requirements are not rigid, otherwise four; corresponding figures for blende-quartz are four and five. For two-mineral separation such as galena and blende from quartz, five compartments will be required to yield relatively high-assay tailing to nine for low-assay tailing with ores in which the mineral is intimately disseminated in the gangue. The number of compartments necessary increases with decreasing size of feed. At Clausthal (*100 J 426*), jigging closely-sized feeds and making lead and zinc concentrates and a tailing, a 4-compartment jig is used on the -11 $+2.8$-mm. size and a 5-compartment jig for the -2.8 $+1.4$-mm. material and also for the classified sands -1.4 mm.

Size of screen compartments depends upon the tonnage to be treated and is not capable of theoretical solution. The area of the screen determines the cross-section of the stream of ore grains passing over the jig, with a given tonnage. The length of the screen determines the time allowed for heavy grains to settle out of the horizontal carrying current, with a given forward velocity of this current. With a relatively short, wide screen surface the rate of travel is low, which compensates for the short horizontal travel, while with a long, narrow screen the rate of forward travel is high but time is afforded for settlement by reason of the correspondingly longer path. The depth of the bed, beyond a certain practical minimum, (p. 678) has no effect on the character of the compartment overflow, but will affect the grade of concentrate taken. The width of the screen is limited by the difficulty of obtaining an even distribution of water in the screen compartment. The practical limits lie between 24 and 36 in. With the width fixed between these limits, the required area is obtained by increasing length. It is better to divide the screen transversely into compartments whose length is from 1.2 to 1.5 times the width than to attempt to get the required area in one or two compartments, even where the exigencies of mineral separation would not require the greater number of compartments. Such division increases the number of draw gates with consequent lessening of the distance traveled by the concentrate to a discharge port and also gives greater flexibility of operation by allowing closer regulation of the grade of material drawn. Large area is particularly necessary for close separation such as between a concentrate and a high-grade middling or between a low-grade middling and a tailing, particularly in the latter case where the low settling rate of the particles makes necessary that they be given a long time to reach the screen.

Representative figures are given in Table 3. The limiting size of jig screen is reached when the jig members become so massive as to be unduly expensive and maintenance becomes difficult. The plunger rods on excessively large jigs break frequently and timber must be used extravagantly to prevent the sides from bulging and leaking.

Table 3. Capacities of fixed-sieve jigs

Plant	Ore	Size of feed, mm.	Tons per square foot per 24 hr.
Bunker Hill and Sullivan	Galena-siderite-quartz	30 to 10	2.4 to 3.2
Doe Run No. 3	Galena-limestone	2	2.5
Gennamari	Galena-limestone	15–4	2.25
Gennamari	Galena-limestone	4–1	2.0
Daly-Judge	Galena-blende-quartz	10–5	4 to 5
Clausthal	Galena-blende-quartz-limestone	8–2	1.8
Wisconsin	Blende-chert-dolomite	10–0	1.5–2

Drop between screens has a material effect on capacity by determining the fall of the horizontal carrying current in the jig and its corresponding velocity and carrying power.

A jig with large drop can handle occasional rushes of feed without choking. A large drop churns up and loosens the bed at the head end with some corresponding effect on the entire bed while a small drop has little or no such effect. In old practice the drop averaged about 1 in. and this figure is probably the best to-day for slow, close work on closely-sized feeds. For rapid work, on roughly sized or unsized feeds, from 2- to 3-in. drop is common.

Height of tail-board determines the depth of the ore bed. This depends, in turn, on the size of particles comprising the bed, the kind of work that is being attempted, the grade of feed, and the difference in specific gravity between valuable and waste mineral. When clean concentrate is desired the bed must be deep; when clean tailing is sought and everything of any value is to be taken in the gate and hutch discharges a relatively shallow bed must be carried. When there is much valuable mineral in the feed the bed may be relatively shallow; with heavy valuable mineral and light gangue a shallower bed may be carried to obtain clean concentrate than when mineral and gangue are more nearly of the same specific gravity. Depth of bed is properly reckoned in terms of number of grains, hence for a given kind of service the actual depth will be greater for coarse feeds than for fine, but the depth reckoned in number of grains will be greater on a jig treating fine feed. In any jig making a gate draw the layer of concentrate must be at least three grains deep, if the cup is set at the minimum height, in order to insure exclusion of middling grains from the pen. This necessary minimum depth will be relatively greater the smaller the particles. The overlying middling layer constitutes the testing zone in which concentrate is separated and must be deep enough to prevent penetration by lighter grains during local disturbances. The required depth will vary from that of the concentrate layer to twice that figure. The surface layer need not be more than one grain deep, but limitation to this depth will require such a high surface velocity in order to move the desired tonnages that it will be difficult to attain complete settlement and saving of the difficult grains. The minimum depth for coarse feeds is, say, seven times the diameter of the larger particles constituting the gate discharge; better twelve, if clean concentrate is to be taken; the depth may be less with the coarsest feeds, if middling only is to be roughed out. With fine feeds (2-mm.) the minimum depth is about 20 times the grain diameter. With much top or cross water the bed must be relatively shallower in order to get rapid removal of values in a soft bed to counterbalance the rapid horizontal flow.

Screen affects the action of the bed and determines the relative sizes of grains in gate and hutch discharges. The screen must be rigid, if boiling of the bed is to be prevented and a uniform thickness of concentrate layer is to be maintained. This requires that the screen be supported on a grate and tacked or wired thereto and that the grate bars be spaced with regard to the flexibility of the screen. The screen should have the maximum possible percentage of opening in order to obtain the highest fluidity of bed with minimum amount of water and also in order to obtain uniformity of water distribution and prevent boiling. The screen openings should be least at the upper surface, to reduce blinding. Punched plate has maximum rigidity and the most favorable shape of opening, it is easily cleaned by a scratching tool and is but little damaged thereby; but woven wire has the greater percentage of opening in the fine sizes. Slotted punching, 1/16 × 5/8-in. to 3/16 × 3/4-in., hit-and-miss endways, is preferred in Joplin. It is placed with the long dimension across the jig. It does not blind so readily as the round-hole, is more readily cleaned, and is stiffer for a given percentage of opening. Grates have been used to a considerable extent to replace screens in the mid-continent mills. Grates are usually made in sections, 6 in. wide by the length of the compartment, and with 1/16- to 3/16-in. spacing. Osage orange wood is used for wooden grate bars because of its hardness and the fact that it does not swell and close the openings between bars. Wooden grates clog less than iron, because they are more smooth and more flexible; they also resist acid water. Life of wooden grates is claimed to be 8 to 12 months under hard service in acid water against two weeks for the iron grates. Grates have less percentage of opening than cloth or punched plate, but they are more rigid, blind less readily and are more easily cleaned.

Size of aperture depends on the size of feed, the place that concentrate is to be taken and the grade of concentrate desired. Coarse feed requires and permits large apertures. Concentration through the screen requires larger apertures than concentration on the screen permits. If apertures are small, small particles will be kept on the screen, thus reducing the size of interstitial spaces in the concentrate bed. The result is to keep fine gangue out of the hutch concentrate and facilitate drawing down fine mineral. Hence a relatively smaller aperture is used when clean concentrate is desired than when the principal endeavor is for clean tailing. With closely-sized feeds the screen aperture is made slightly less than that of the sizing screen preceding except that the jig-screen aperture is rarely less than 2 or more than 5 mm. With unsized feeds or feeds with a large range between upper and lower sizes, the aperture is determined to a considerable extent by the character of work desired and the minerals in the feed. In Wisconsin a typical set of screens on an 8-cell rougher jig, treating 3/8-in. lead-zinc feed and making practically all concentrate from the hutch is 1/8, 3/16, 1/4, 1/4, 1/4, 3/16, 3/16, 3/16-in. The screens on the following 7-cell cleaner had 3/32, 1/8,

3/16, 3/16, 3/16, 1/8 and 3/16-in. apertures. When a jig is run to take all of the concentrate through the screen the aperture is made slightly larger than the largest particle in the feed and a bed of proper specific gravity, composed of particles larger than the apertures, is placed on the screen before jigging starts. In such practice at CLAUSTHAL, with a feed between 2.8- and 2-mm. the screen apertures were 3- to 4-mm.; with feed 2- to- 1.4-mm., the apertures were 2- to 3-mm.; four grades of sand finer than 1.4-mm. were jigged on and through 1-mm. aperture.

Grids for supporting the screens are made of wood or cast iron. The slats are placed from 1 to 6 in. apart according to the amount of support required, and should run at right angles to the length of the jig so that they will be parallel to and not cause eddies in the plunger-water currents. Wooden slats should be beveled to an edge at the top to lessen the area of dead space above them. Where there is much acid in the water wooden grates are practically essential. Grids and screens should be readily removable. This can be done by making the screen-compartment liners in four pieces and holding them in place with wedges, as shown in Fig. 2, and making the hood (gate) also readily removable. Then by having rings wired to the grate and a small grappling sling suspended from a tackle above the jig, a screen may be quickly removed with most of the bed in place and this can be subsequently dumped on the replacing screen, allowing the first to be cleaned or changed at leisure. Screens are frequently sloped 1 to 2 in. in their length toward the discharge end in order, by greater depth, to compensate for impoverishment and maintain uniform resistance to the water currents.

Concentrate draws. The best known is the gate-and-dam shown in Fig. 3. Discharge is prevented until there is a sufficient bed of heavy mineral formed to seal the opening between the lower edge of the gate and the screen. When the dam is lowered discharge begins and continues until a condition of equilibrium is reached, when the hydrostatic head of the column of heavy mineral (H) within the pen, when in partial suspension in the upward current and therefore free to flow, is just less than that of the composite column of heavy mineral, middling (M) and light mineral (L) without, friction losses due to flow of the bed of heavy material across the screen and under the gate constituting a deduction from the head of the bed outside the pen. With any given setting of the dam, increase in the amount of heavy mineral in the bed will cause corresponding increase in flow over the dam, decrease will cause cessation. This type of draw is usually placed at the front side of the screen compartment near the discharge end. Thus placed it requires that most of the concentrate shall travel at an angle more or less acute to the forward travel of the overlying bed as a whole, part of it at right angles and a certain part must actually travel against the stream, if it is to discharge. The result is necessarily some loss of free mineral over the tail-board of the compartment, but the most serious objection to this placing of the draw is met when concentrate must be removed rapidly. Under these circumstances there is a steep slope of the surface of the concentrate layer down to the bottom edge of the pen. This results in boiling at this point and consequent contamination of the concentrate by material from the overlying layers. This type of draw is sometimes placed at the discharge end of the compartment with the concentrate-discharge spout running in the compartment partitions. This placing is superior in so far as removal from the bed is concerned, but will give some trouble by clogging. Fig. 10 shows a pipe draw designed on the same principle. It makes the concentrate travel in a less favorable path than the side draw. The portion of the jig bed adjacent to any draw is coarsest. This produces a "live spot" in the bed that will permit gangue to pass down into the hutch, and wear on the screen is greatest at this point, which aggravates the trouble. The size of the pen in discharges of the gate-and-dam type and of all ore passages should be sufficient to allow free movement of impounded material, *i.e.*, at least three times the diameter of the largest particles, better more. There are a number of other draws whose fitness may be tested according to the method of analysis given.

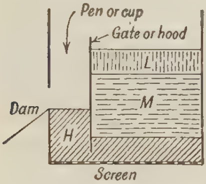

FIG. 3.—Gate-and-dam jig discharge.

Hutch draw must be capable of close adjustment in order that suction may be carefully controlled. Such adjustment results in frequent clogging, hence the draw should be of such variety that it can be opened wide to remove such obstruction. When the ordinary pipe-and-plug spigot is used, the working plugs can be fitted into the center or bottom of a 6-in. plug, which is readily removed when necessary. The ordinary molasses gate, 1½- to 3-in. sizes, is frequently used. Rotating slush gates (Fig. 4) are common when continuous hutch discharge is to be maintained.

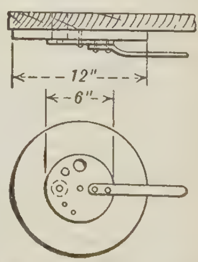

FIG. 4.—Slush gate for jig hutch.

Plunger is ordinarily made with the same area as the screen. This gives symmetrical construction, minimum velocity changes in the water currents, and readily understood adjustment. There is some advantage in making the plunger larger than the screen, which allows shorter plunger stroke and larger throat, thus producing a free action in the beds and reducing power consumption. For most efficient mechanical operation the plunger should fit its compartment as snugly as possible without binding. The usual fit is between 1/16 and 3/16 in. clearance all around. Small plunger clearance creates strong suction and where this is undesirable a close fit must be compensated by plunger valves, otherwise excess back water must be used to cut down suction. A loose plunger requires a longer stroke than one that is tight-fitting. Clearance must be greater when water is fed above the plunger than when introduced below. Introduction of water below the sieve is likely to cause collection of air under the plunger with consequent uneven action. Plungers are built up of five courses of 1-in. tongue-and-groove stock, thoroughly wet with good white-lead or asphalt paint, laid with alternating courses at right angles and closely nailed. The outer courses are cut shorter than the center to allow for rocking of the eccentric. Courses both sides of the center course are shortened about 1/8 in. all around to provide water packing. Eccentrics should be of extra-heavy pattern with spherical sliding surfaces to prevent binding. They should be evenly spaced around the shaft. It is a convenience if they are graduated to show length of stroke. The bottom of the plunger should never rise above the sieve.

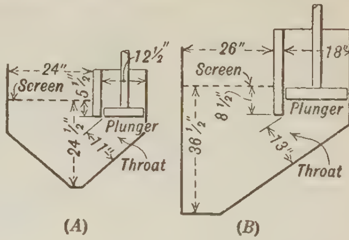

FIG. 5.—See Table 4.

Longitudinal partition. The position of the lower edge determines the changes in velocity of the water currents and thereby influences the distribution of water. The best position is with the distance from the lower edge to hutch walls equal to width of plunger and screen compartment. There is then minimum velocity change. The lower edge of the partition should extend at least 0.4 times the width of the screen compartment below the screen in coarse jigs and 0.33 times in fine jigs (*Richards*). Table 4 shows what can be done by attention to these details and the penalty for failure.

Jig box and frame. All dimensions are substantially fixed by the rules already set down. The hutch product cannot be drawn clean unless the bottom is hoppered both ways to the draw valve. The usual practice is to carry the front wall straight down. The walls should be not less than 3-in. surfaced plank, except for very small jigs. Even with this weight there will be some bulging with long strokes if the compartments are long and the span of the planks correspondingly great. All planks should be carefully tongued and grooved or grooved and joined with close-fitting feathers, and the joints should be set in white lead. Transverse partitions should be dapped into the walls and the center-board dapped into the transverse partitions. Fig. 6 shows a cheaper method of wall construction, using 2 × 3- or 2 × 4-in. scantlings set in paint and packed with wicking, then securely spiked. This is particularly suitable for bull jigs (Art. 5), which would require very heavy planking. Posts should be at least 6 × 6-in. better 6 × 8-in. in large jigs, with caps and sills the same width and one or two inches deeper. Mortise the posts into cap and sill, but provide for draining the sill joint. Transverse tie rods should be bored through the body of a transverse plank rather than let in in place of a feather, otherwise a difficult leak will occur. Strap bolts (Fig. 2) are easier to put in and just as satisfactory as through rods from cap to sill. Floor-space may be saved by placing jigs back-to-back, or face to face. Jig walls are sometimes built of reinforced concrete about 4½ in. thick. (*109 J 1115.*)

Transmission machinery. Shaft should be 2 7/16-in. minimum for fine jigs with compartments up to 36-in. length; 3 7/16 will carry a long-stroke plunger on a 48-in. compartment. Pulleys should be keyed and set-screwed, and of ample face. Tight-and-loose pulleys should always be provided. Common flat boxes will serve but adjustable ball-and-socket bearings will pay for themselves many times over in ease of maintaining alignment.

3. Operation of Harz jigs

The important operating factors are: length of stroke, number of strokes per min., screen aperture, depth of bed, size and character of bedding material, quantity of cross and back water, size and richness of feed, capacity and power consumption. These factors are closely dependent. Rate, size and richness of feed are fixed in any given case by the character of the ore and the

design of the mill; screen aperture, speed and depth of bed are parts of the jig design; the only variables within the control of the jig operator are length of stroke, character of bedding and quantity of water.

Jig operation requires more skillful labor than other forms of gravity concentration. Shut-downs should be as infrequent as possible, since it may easily require an hour or more to get back to good operating conditions after starting-up again.

Length of stroke is directly dependent upon the number of strokes per minute, unless the latter are so few that there is an appreciable rest period between pulsations. In any case the length of stroke must be sufficient to produce a certain amount of fluidity in the bed, *i.e.*, it must be sufficient to cause the bed to be lifted and the grains spread apart enough to allow interstitial settlement.

If the jig is running at relatively high speed, the length need not be so great as when low speed is used because of the greater velocity and hence greater lifting effect of the high-velocity current. For a similar reason length of stroke at a given speed need not be so great for light ores as for heavy ores. When the endeavor is to make clean concentrate the bed should be maintained as compact as is compatible with the desired recovery by using a short and rapid stroke and pulsion should be accented by using a large amount of back water; on the other hand, when clean tailing is the desideratum, the bed should be kept loose by long, slow strokes and strong suction obtained by the use of little back water. The effect of reduction in back water is shown in Table 5 (*17 A 637*). A relatively

Table 5. Effect of reduction of water on work of a fixed-sieve jig

short, rapid stroke with much back water is used for rich, heavy feed, while for low-grade feed, a long, slow stroke and little water are usual. Hence, a rougher jig requires a longer stroke, lower speed, and less back water than the corresponding cleaner. For separation of low-grade middling from tailing the usual practice is a long, slow stroke, shallow bed and a small amount of back water. This adjustment also has the result of overcoming the bad effect of the large volume of cross water on the later compartments. In the Wisconsin zinc field the operators test for the necessity of change in stroke by increasing the specific gravity of bed; if this raises the grade of concentrate, stroke length should be decreased.

With a given maximum size of particle, unsized feed requires a shorter stroke than sized feed because of the greater lifting effect of the water when the interstices of the bed are filled with fine material. Similarly a fine screen retains more fine material in the bed and shorter stroke can be used. High speed accompanies short stroke in order to maintain capacity. If a long stroke is used with unsized material, the bed is loosened so much that it boils and fine gangue is drawn down on the return stroke. If the bed becomes impoverished, there is a tendency to mat and choke the sieves, hence with low-grade feed, it is best to maintain a bed of coarse concentrate. Coarse feed requires a longer stroke than fine feed. Flat and thin pieces (floaters) require a short, rapid stroke, a thin, loose bed, and as little cross water as possible. Speed must be kept uniform or it will be impossible to hold a bed on the sieve. Excessive cross water must be avoided, if tailing loss is to be kept down and the jig beds are to be kept in good condition. Where large amounts of plunger water are required to keep down suction, there will be excessive cross water on the later compartments unless special means are taken to rectify the condition. Water may

be drawn off above the level of the bed. A long jig may be broken near the center and the feed dewatered between the two parts, but this involves lost head room and increased floor space.

Bedding, sometimes called RAGGING when not formed by the jig itself from the feed furnished, is the layer of heavy material lying at the bottom of the mass of grains on the jig screen. The word BED is used indiscriminately to describe this layer and also the whole mass of grains on the sieve; ordinarily the context will make the usage definitive. The important characteristics of the bedding layer are its thickness and the size and specific gravity of the grains.

The function of the bed is twofold: (1) to act in the fashion of a liquid seal for the concentrate cup, and (2) to serve as a screen when hutch concentrate is made. In the first case the desideratum is a semi-fluid whose specific gravity is greater than that of the grains to be excluded and not greater than that of the grains to be received. These requirements are best satisfied by a bed consisting of grains of the same material from which concentrate is being made, and of mixed sizes so that the lifting effect of the water will be a maximum, with consequent maximum fluidity. If the specific gravity of the bedding grains is greater than that of the concentrate to be made, excessive pulsion will be required to produce movement and this results in boiling of the overlying material and disturbance of the work of the jig. A similar result follows if the bedding is too coarse or of too great uniformity of size.

The thickness of the bed is determined in part by the size of concentrate grains and the consequent setting of the concentrate cup, in part by the requirements as to cleanliness of concentrate, and in part by the specific gravity of the bedding grains. The bed must be thick enough to effectually seal the cup against the entry of low-grade material and this means, practically, that the surface should be three or four grains higher than the bottom of the cup, except in the case of the coarsest feeds, and from 0.5 to 1 in. higher in the case of fine feed. To make clean concentrate requires a deeper bed than otherwise.

Beds of low specific gravity tend to bank up against the tail-board, hence, unless special precautions are taken such as inclining the screen against such flow or placing baffles across it at intervals, it will be necessary to use a thin bed with material of low specific gravity.

When jigging through the screen the interstices in the bed determine the size of grains that can pass and, in conjunction with other operating features, the strength of suction. Bedding grains about three times the diameter of the maximum grain it is desired to draw down are provided. Maximum suction is attained with maximum interstices, hence coarser and more uniform bedding is used on the later sieves, where clean tailing is sought and the grade of hutch product is of minor importance. If the valuable mineral abrades readily, grains of more durable material of the same specific gravity are frequently supplied for bedding; thus iron balls or punchings or lead shot will form a satisfactory bed for making galena concentrate, pyrite or magnetite for chalcopyrite or blende, and feldspar for slate in coal jigging. On the later compartments of a jig the bedding grains are usually middling grains of proper specific gravity, but artificial bedding is sometimes provided. At CALUMET AND HECLA middling grains were used to bed finishing jigs treating the hutch products of primary jigs that bedded themselves. If the bedding grains are much heavier than the concentrate, as, for instance, when iron slugs are used as bedding for pyrite or blende, the bedding is not lifted on the pulsion stroke and merely serves to decrease the sieve openings.

An ore that makes a small percentage of concentrate requires a thick bed; a high-grade ore gives satisfactory results with a thin bed and heavy suction.

Feeding. The principal requirements are that the feed rate be regular and that the material shall be spread evenly over the entire width of the screen. Automatic discharges for taking concentrate from above the screen respond slowly to changes in concentrate supply, with the result that a sudden increase in feed rate or metal content causes valuable mineral to pass over the tail-board, while sudden decrease will cause the discharge of low-grade material from the cup. When making hutch concentrate only, increase in feed rate will cause increased tailing loss, decrease will cause some lowering of the grade of the concentrate, but this will not be serious. Uneven distribution of feed puts the task of distribution on the jig with consequent decrease in capacity.

Power is dependent primarily upon sieve area, speed, length of stroke, depth and weight of bed. *Wiard* gives the formula, $HP = AD^{1/2}/5000$, where A is the sieve area in sq. in. and D is the diameter of feed in mm. For estimates, 0.1 to 0.15 hp. per sq. ft. of total sieve area is safe.

Water consumption varies with the size of feed, specific gravity of the minerals, depth of bed, size of screen aperture, number and length of stroke, and according to whether pulsion or suction is accented. *Wiard* gives the roughly approximate empirical formula, $G = (DA)^{1/2}/3.03$ where D is the diameter of feed in mm. and A is the area of screen in sq. in. and G = gal. per min.; the result tends to be low.

Three-compartment, 24 × 36-in. jigs treating 3-mesh lead-zinc ore at Daly Judge used about 11,000 gal. per 24 hr. treating 75 to 90 tons. Two-compartment, 24 × 36-in. jigs at Doe Run No. 3 mill treating classified feed used 30 gal. per min. each, treating 30 tons per 24 hr. At Gennamari a 4-compartment, 36 × 42-in. jig treating −15 + 4-mm. lead ore required 100 gal. per min. for 45 tons per shift. Jigging − ⅜-in. blende, a 5-compartment, 30 × 42-in. jig required 150 to 200 gal. per min.

Performance. Jig settings used for the treatment of closely-sized lead-zinc ores at Clausthal (*100 J 425*) are given in Table 6. Practice on a lead-silver ore at Silver

Ag, 32 per cent. Pb. Sand jig (No. 5): 1st compartment: 31 oz. Ag, 53 per cent. Pb; 2nd compartment: 11 oz. Ag, 15 per cent Pb, 26 per cent. Fe.

and − 3-mm. de-slimed. The bull jig (30-mm.) has four compartments, 25½ × 33½-in., fitted with 5-mm., 15-gage round-hole plate, life, 30 days. The jig makes 150 @ 1½-in. strokes per min. Treating feed carrying 8.3 per cent. lead and 50 per cent. moisture at the rate of 96 tons per 24 hr. it produces a middling assaying 18 per cent. lead from the

cups, and a tailing assaying 0.86 per cent. Pb. The beds are 6.5 in. deep. Water consumption, 850 gal. per min. Attendance, twelve machines per man. Lost time, 0.009 per cent., due to changing screens and liners. The (15-mm.) jig is 4-compartment, 25½ × 33½-in., fitted with 3-mm. round-hole 17-gage plate on all compartments; life of screens, 30 days; speed: 200 @ 1-in. strokes per min. with 5½-in. beds. The feed carries 50 per cent. moisture. Water consumption, 850 gal. per min. Feed rate, 48 tons per 24 hr. One man attends twelve machines. Assays, per cent. Pb: Feed, 14; tailing, 1.5; concentrate, 60; middling, 11.0. The (7-mm.) jig is 4-compartment with the first compartment 25½ × 37-in. and the others 25½ × 33½-in.; 6-mesh, No. 16 or No. 17 brass wire screen is used and lasts 180 days. Feed contains 50 per cent. water. Speed, 225 @ ¾-in. strokes per min. with 4½-in. bed. Feed rate, 72 tons per 24 hr. Water consumption, 624 gal. per min. Twelve machines per man. Assays, per cent. lead: Feed, 8; tailing, 1.2; concentrate, 70; middling, 10. The (3-mm.) jig is 4-compartment, same size as the preceding with 8- mesh No. 16 or No. 18 brass-wire screens which last 180 days. Feed is between 3-mm. and 20-mesh (0.833-mm.) and contains 50 per cent. water. Feed rate, 48 tons per 24 hrs. Water consumption, 624 gal. per min. Speed, 250 @ ¼-in. strokes per min. with 4½-in. bed. Assays, per cent. Pb: Feed, 7.5; tailing, 1.5; concentrate, 75; middling, 8. One man attends twelve machines and in case of all jigs controls the water supply and concentrate-discharge rate. The old practice at this mill (*2 MM 364*) was to make two sizes only for jigging, *i.e.*, −30 +10-mm. and −10-mm. A 4-compartment bull jig of the same size as at present treated 60 to 80 tons per 24 hr. with 155 @ 1⅝-in. strokes per min. and from a feed carrying 10 to 18 per cent. Pb made concentrate assaying 52 to 59 per cent. from the first cup, 40 per cent. from the second cup, middling assaying 8 per cent. from the third and fourth cups and tailing assaying 1.0 to 1.4 per cent. A 5-compartment classifier jig treated the 10-mm. undersize. It had 2-mm. plate on the first two compartments and 3-mm. plate on the others. Speed was 225 @ ⅝-in. strokes per min. Concentrate from the first cup assayed 65 to 73 per cent. lead; second cup, about 40 per cent.; third and fourth cups, about 10 per cent.; fifth cup, 5 per cent.; slime overflow from the first compartment, 14 per cent.; first hutch, 55 per cent.; second hutch, 30 per cent.; hutches 3 to 5 combined, 7 per cent.; tailing, 1.4 to 1.8 per cent. Table 8 is a sizing-assay test of the combined hutch product of this jig, showing a characteristic dip in assay values in the middle sizes. Table 9 shows the particle-size distribution in the various hutches.

Classification of No. 1 hutch product in a free-settling classifier yielded a spigot product containing 77 per cent. lead and an overflow containing 49 per cent.; corresponding figures for the second hutch were 60 per cent. and 12 per cent. Table 10 is a sizing-assay test of the tailing from the same jig. At FEDERAL MINING AND SMELTING CO., Morning mill a feed all passing 1-in., 30.5 per cent. on 12-mm., 68.3 per cent. on 4-mesh and 1.2 per cent. on 6-mesh, containing 42 per cent. water, was treated on a 2-compartment 18 × 34-in. jig, fitted with 5-mm. punched plate. Speed was 158 @ 1.5-in. strokes per min. Bed, 6 in, thick. Tons per 24 hr., 200. Power, 1 hp. One man attended 6 jigs, 6 rolls, and the accompanying trommel equipment. He controlled stroke adjustment, water regulation and thickness of bedding. Lost time amounted to 0.05 per cent., principally due to screen changing. Life of screens was 90 days. Feed assayed 6.5 per cent. Pb; concentrate, 45.0; middling (no tailing), 4.5. Table 11 is typical of the lead-hutch concentrate to be expected

in jigging a fine feed containing both lead and zinc. On this type of ore at VAN ROI MILL (*101 J 464*) jig feeds average 5 per cent. Pb, 7 to 15 per cent. Zn and 10 to 20 oz. Ag; jigs treating sized feeds at 16, 10, 7, 4 and 3-mm. make tailing averaging 0.5 to 1.0 per cent. Pb, 3 per cent. Zn and about 3 oz. Ag; lead concentrate assays 60 to 70 per cent. Pb, zinc concentrate about 40 to 45 per cent. Zn. About 70 per cent. of the tailing in this mill is made on the first four jigs and 20 per cent. on the finer jigs. Table 12 gives operating data on jigs treating complex lead-zinc ores at U. S. SMELTING, REFINING AND MINING CO., Midvale plant. At GENNAMARI, Sardinia (*100 J 794*) coarse jigs treat − 15 + 4-mm. material and fine, −4 +1-mm. The coarse jigs are 4-compartment, 36 × 48-in., making 1 ton of 55-per cent. Pb concentrate from the first cup and hutch, 20 tons of 5-per cent. middling from the last three compartments and 24 tons of tailing with a trace of lead, per shift. The fine jig is 5-compartment, 31 × 43-in., treating 40 tons, half primary and half re-ground middling, per shift, making 1 ton of 65-per cent. concentrate, 4 tons of 5-per cent. middling and 35 tons of tailing with a trace of lead. Table 13 shows highly efficient practice in jigging fine material but the high metal content in the finest size demonstrates one reason why tables and other concentrating processes have replaced jigs in treating fine feeds. Table 14 shows the results of re-treatment of the fine lead concentrate from the preceding operation. Treating a TUNGSTEN ORE consisting of ferberite in quartz and granite gangue (*101 J 717*), assaying 0.75 to 1.5 per cent. tungstic oxide, sized to − 0.5 + 0.25-in. and − 0.25-in., in a 2-compartment jig with 18 × 30-in. sieves, making 110 to 200 @ 1.25- to 1.5-in. strokes per min., with a 4-in. bed on 12-mesh screen, feeding at the rate of 6 to 10 tons per 8 hr., concentrate from the first screen assayed 50 to 55 per cent. tungstic oxide, second screen, 30 per cent. and hutch 1.5 to 3 per cent. Concentrate was skimmed by hand. The second concentrate was sometimes thrown back on the first screen. Water consumption was about 150 gal. per min. At CANANEA 17 @ 2-compartment double concrete jigs, 24 × 36-in., were used to treat a feed sized between $\frac{3}{16}$-in. and 100-mesh. The jigs were fitted with 5-mesh, No. 14-brass-wire screen (life 50 days), and carried 4-in. beds. Speed, 170 @ 1-in. strokes per min. One hp. ea. Feed rate, 70 tons per 24 hr. Water, 240 gal per min. One man attended three machines. Lost time, 0.25 per cent., due principally to changing screens. Assays, per cent. Cu: Feed, 1.60; tailing, 0.9; concentrate, 3.5. A one-compartment, 18 × 28-in. jig treating a DISSEMINATED COPPER ORE sizing 3.9 per cent. on 10-mesh, 5.4 on 14,

from Wilfley and Butchart tables; average size, 6 per cent. on 10-mesh. Jig screens were woven brass wire with 0.67-in. opening and lasted 60 days. Speed 190 @ ¾-, ⅝- and ½-in. strokes per min. 3.5-in. bed. 100 tons per 24 hr. Water, 75 gal. per min. in hutch and 75 per cent. moisture in feed. 3 hp. One man attended 10 machines. Assays, per cent. Cu: Feed, 6; tailing, 2; concentrate, 15.

4. Cooley jig

Description. This is a variant of the Harz type used extensively in the mid-continent zinc fields. The only essential difference from the ordinary Harz jig lies in the fact that the jig is almost always used to make hutch only and no screen discharge is provided. Coarse concentrate and middling are shoveled off intermittently as operation demands. Attempts to run with continuous draw of bed concentrate result in hard beds with impaired jigging action and the discharge of a large amount of low-grade material. If the amount of coarse concentrate and middling is large, it is usual, in the case of the middling at least, to use a coarse screen and jig through an artificial bed, using long stroke, low speed, shallow bed and high drop between screens.

Construction. The usual method of construction is cheap and highly efficient. The floor is built up of 3 layers of 1-in. T-and-G boards laid in white lead or asphalt paint and nailed flat; walls and partitions are 2 × 4-in studs, dressed, laid flat and nailed, with two strips of cotton wicking, saturated with white lead, laid between. The front of the hutch is stepped out 8 to 10 in., then carried up straight. The walls of the plunger compartment are carried up to give support to the journal boxes and to prevent splashing. The entire jig is lined with 1-in. boards and these are also used to form a sloping bottom for the hutch. The usual sizes of screen compartments are from 20 to 42 in. wide by 24 to 48 in. long with 6- to 9-in. tailboards on the first compartment ranging down to 5- or 6-in. on the last. Practice as to depth of bed varies. A deep bed requires much water, which sends fine free mineral to the later cells. These are made hard by the swift flow of excess top water and as a result the fine mineral goes into the tailing. Excess top water in the tail end of the jig may be eliminated by breaking the jig in two and de-watering before the last cells. A common drop in the 30 × 36-in. size is 1¾ in. In a 42 × 48-in. jig at the Media mill, a 3-in. drop was used. Rougher jigs are run at 90 to 125 @ ⅝- to as much as 2½-in. strokes per minute; cleaners at 160 to 200 @ ⅜- to ¾-in. strokes, and sand jigs at 150 to 190 @ ⅛- to ½-in. strokes. Some mills use special chat jigs of 4 to 5 cells run at higher speed and shorter stroke than the cleaner jigs. Typical adjustments are shown in Table 15. In some cases the drive shaft is in two sections and the head end is driven at 20 to 30 r.p.m. less than the tail end. Punched-plate screens are commonly used. The sieves are sloped

downward toward the tailing end, as much as 1 in. in their length, in order to compensate for the greater weight of concentrate at the head end and prevent uneven water distribution.

Number of compartments. Jigs used to make clean concentrate and tailing on ⅜-in or ⅝-in. screen undersize (one-jig mills) are 7- to 9-compartment. In such a jig, cell No. 1 is used for clean lead concentrate, cell No. 2 makes a lead-zinc middling that is either circulated or re-ground; cells 3 to 5 produce clean zinc concentrate and, in a 9-cell jig, cells 6 and 7 are also used to make clean zinc; the last two cells produce middling for re-grinding. The greater number of cells is used for high-grade feeds or with ores containing much lead; in the latter case cell No. 3 may also make middling and cell No. 4 may be the first zinc cell.

6	240	⅛	⅜	6	¾
7	240	3⁄16	7⁄16	7	¾

Single-jig treatment is suitable only for low-grade, coarsely-disseminated ores low in lead. If there is much lead it will appear in the zinc concentrate. With the 2-jig arrangement the combined hutch products of the first or rougher jig carrying 10 to 25 per cent. zinc, locally called SMITTEM, are sent to the cleaner. Tailing is discarded. Table 16 shows typical feed and tailing of a rougher jig. Some, but very little blende finer than 200-mesh is caught on these jigs and about 30 per cent. of the zinc in the tailing is this fine material. Finished concentrate, assaying 75 to 80 per cent. lead, is taken from the first hutch of the cleaner, the second hutch is sent back to the head of the cleaner, hutches 3 to 6 are clean zinc concentrate assaying 50 to 60 per cent. zinc, and hutch 7 is returned to the head of the cleaner or re-ground, depending upon whether the values are free or locked mineral. The latter material is locally called CHAT and assays from 4 to 8 per cent. zinc. Table 17 gives typical sizing-assay test on cleaner-jig zinc concentrate. The cleaner tailing is either thrown away or sent to a sand jig of 3 to 5 cells, usually of smaller grate area than the cleaners.

Operation. All jigs are run with strong suction, which is enhanced by leaving the hutch gates partly open. To make rich lead concentrate requires high-grade feed. There is an advantage in sending the first rougher-jig hutch to a small separate jig, otherwise it is necessary to build up the grade of the cleaner feed by circulation of the lead concentrate. Water consumption ranges from 800 to 1200 gal, per min. for a 7- to 9-cell jig. A common figure for estimate is 1500 to 2500 gal. per ton treated. The capacity of a rougher is from 8 to 12 tons per sq. ft. of screen surface per 24 hr.; for a cleaner 3 to 4; for a single-jig mill, 4 to 5 tons.

Performance. JOPLIN DISTRICT (*57 A 446*): Rougher jig on sheet-ground ore: Feed, 2.85 per cent. Zn; concentrate, 25.5 per cent.; tailing, 1.10 per cent. (dewatered 0.70 per cent.); recovery, 64.17 per cent. On lower-grade ore: Feed, 1.13 per cent. Zn; rough concentrate, 15 per cent.; tailing, 0.50 per cent. (dewatered, 0.38 per cent.); recovery,

57.67 per cent. Hard ground other than sheet: Feed, 1.20 per cent. Zn; rough concentrate, 9.57 per cent.; tailing, 0.55 per cent. (dewatered, 0.34 per cent.); recovery, 57.47 per cent. In general clean concentrate assays 50 to 60 per cent. Zn; the locked middling particles from rougher and cleaner jigs combined, 4 to 8 per cent. In the Wisconsin district (*111 J 1065*) the average recovery from 1.75-per cent. Zn feed is 55 to 60 per cent. in a 48-per cent. concentrate; tailing averages about 0.6 per cent. Zn, of which the part on 10-mesh runs about 0.4 per cent. Zn, the +40-mesh, 0.95 per cent., and slime, 8 per cent. On 6-per cent. feed through ⅜-in., jig mills in this district make 65 to 70 per cent. recovery in a 45- to 50-per cent. concentrate carrying less than 3 per cent. CaO ; about 75 to 80 per cent. of the concentrate is +20-mesh. At American Zinc, Lead and Smelting Co. mill at Mascot, Tenn, bull jigs, rougher and cleaner jigs and sand jigs are used. The bull jig is 3-compartment, 36 × 48-in., fitted with 10-gage steel-plate round-hole screens with 0.5-in. aperture (life, 185 days). Speed, 82 @ 2-, 1.75- and 1.5-in. strokes per min. Feed, 300 tons per 24 hr. 358 gal. wash water per min., 8- to 12-in. beds. Power consumption, 9 hp. The feed is tailing of a 6-cell rougher jig, all through 0.5-in., dewatered to 34 per cent. moisture on ⅛ × 1-in. Rek-tang screen. All hutches are run open. One operator attends 4 machines. Assays, per cent. Zn: Feed, 1.25; tailing, 0.8; middling (no concentrate), 3. The rougher jig is 6-compartment, 32 × 44-in., fitted with 14-gage punched-slot steel plate, apertures ⅛ × 1-in. (life, 92 days). Feed is all through 0.5-in. aperture and contains 37 per cent. water. Speed, 110 at 1⅝-, 1⅝-, 1½-, 1½-, 1⅜-, and 1⅜-in. strokes on the 6 compartments respectively. The beds are 8 to 10 in. deep. Wash water, 460 gal. per min.; power, 18 hp.; feed rate, 600 tons per 24 hr. Assays, per cent. Zn: Feed, 3.8; tailing, 1.25; middling (no concentrate), 7.0. One man attends 2 machines and regulates plunger water and thickness of bed. The cleaner jig takes the middling from the rougher. It is 7-cell, 28 × 42-in., fitted with cast-iron grates with 1⁄12- and 1⁄16-in. slots (life, 50 days). Speed of the first four plungers is 180 r.p.m. and of the last three, 200 r.p.m. Stroke lengths from head to tail end are ⅝, ½, ½, ½, ½, ⅜ and ⅜ in. Beds are 7.5 in. deep. Feed rate, 200 tons per 24 hr.; 68 per cent. moisture in feed; 552 gal. per min. of water added; power consumption, 21 hp. One man attends 2 machines. Assays, per cent. Zn: Feed, 15; tailing, 4; concentrate, 62. The

3-compartment, 28 × 42-in. sand jig treats re-ground middling passing a ⅛-in. trommel. It is fitted with cast-iron grates, 1/10- and 1/12-in. slots (life, 60 days). Speed, 200 @ ⅜-, ⅜- and ½-in. strokes per min.; 7.5-in. bed; 150 tons per 24 hr.; 9 hp. Feed contains 85 per cent. water and new water is 391 gal. per min. One man operates 4 machines.

5. Other fixed-sieve jigs for treating metalliferous ores

Collom jig is of the fixed-sieve type with a special plunger mechanism that gives a quick downward stroke and retarded return. The mechanism has link-operated rocking hammers that strike the plunger rods down sharply against the pressure of springs which return the plunger more slowly on expanding. The plungers may be fitted more tightly than the eccentric-driven type, because of their non-rocking travel, but the mechanism is more complicated and less rugged than the simple eccentric. The jig is built double with sieve compartments on the outside of the plunger compartments, and these are about half the area of the sieve compartments and are placed side by side. This causes maximum water effect at the feed end of one compartment, which is not distinctly harmful, and at the tailing end of the other compartment, which is harmful.

Dee jig (Fig. 6) has a hopper-shaped valved plunger under the screen with the plunger rod passing through the center of the screen. The valved plunger decreases suction and gives uniform distribution of water currents, but at the expense of great inconvenience in operation and maintenance.

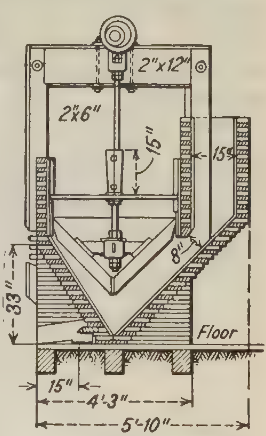

Fig. 6.—Dee jig.

Evans jig is of the Harz type and embodies no essential departures from the standard form except that the eccentric is designed to maintain the plunger in horizontal position. It has been largely used at Anaconda mills.

Exhaustive comparative tests with Harz jigs at this plant showed no conclusive difference in metallurgical results, but considerably higher tonnage treated per square foot of sieve area on the Harz jigs. Average results of one such comparative run are given in Table 18.

Hodge jig is of the Harz type but has a mechanism for attaining differential plunger motion similar to that on the Deister No. 3 slime table (Sec. 10, Art. 7). It has been used to a considerable extent in the Lake Superior copper mills. It is built in cast-iron double units which are set up in pyramid arrangement.

Table 18. Comparison of Harz and Evans jigs at Anaconda. (Treating de-slimed undersize of 4-mesh screen)

Evans.....	11	3	26×41	231.6	0.95	8423	1.43	0.71	7.73

Performance. At Copper Range mills four double Hodge jigs with 24 × 36-in. compartments are used in series. They are fitted with double-crimped brass-wire screens of the following sizes: 8-mesh, No. 18 wire on No. 1 (life, 324 days); 10-mesh, No. 20 wire on No. 2 (life 405 days); 12-mesh, No. 21 wire on No. 3 (life, 260 days); 14-mesh, No. 22 wire on No. 4 (life 260 days). Speed of all jigs, 165 strokes per min., @ ⅞-, ¾-, ⅝- and ½-in. respectively, with 2.75- to 3-in. beds. Capacities: First sieve, 21 tons per 24 hr.; second, 16; third, 9; fourth, 6. Water consumption varies from 160 gal. per min. on No. 1 to 100 gal. per min. on No. 4. Power consumption, 0.52 hp. per sieve. Feed contains 80 to 85 per cent. water. Assays, per cent. Cu: Tailing, 0.5; concentrate, 65.

Slide jig has a Whitworth quick-return plunger mechanism arranged to give accelerated down stroke and retarded return, thus emphasizing pulsion and lessening suction. Otherwise it differs in no way from the typical Harz jig.

May jig (*27 IMM 338*) is of the fixed-sieve, plunger type with rocking-arm drive, arranged with plunger compartments between the sieve compartments. It is extensively used for treating the silver-lead-zinc ores of the Barrier district of Australia; for this service it has supplanted all other varieties after extensive testing. The usual practice is to treat the de-slimed undersize of a 3-mm. screen on three to five 30 × 42-in. compartments, the last being for tailing discharge, making all the concentrate from the hutch, bed-

ding the screens about 1.5 in. deep with iron punchings $\frac{5}{16}$- to $\frac{3}{8}$-in. diameter. Punched-plate or woven-wire screen with about 4-mm. apertures on the first compartment and 3- or 3.5-mm. apertures on the later compartments is used; brass grids 1.75 in. deep and with 2.5 × 5-in. pockets are used to hold the bed in place; speed varies from 180 to 240 r.p.m. The plunger area is about 40 per cent. that of the screen; plungers are fitted with board clack valves to lessen suction.

The ore of the district consists principally of galena, blende, rhodonite and quartz. Two methods of treatment are practiced; in the first a coarse galena concentrate only is sought and but two or at most three screen compartments are necessary; in the second a 5-compartment primary jig is followed by a 5-compartment secondary, the rougher makes clean galena concentrate in the first and second hutches, in the third, a middling containing free mineral which is returned to the head of the jig, true middling in the fourth for re-grinding and treatment in the secondary jig, and from the fifth tailing for re-grinding and fine concentration. The secondary jig makes a final quartz tailing. At the Zinc Corporation plant (*118 P 89*) a 3-compartment primary jig makes a 66-per cent. lead concentrate from the first two hutches and a 6-per cent. tailing from the third. At Broken Hill South (*27 IMM 337*) a double 3-compartment jig makes products as shown in Table 19. Capacity in this service varies from 12 to 14 tons per hr.

Table 19. Products of May jig at Broken Hill South mill

Hutch number	Product	Destination	Assay		
			Lead per cent.	Silver, oz.	Zinc, per cent.
1	Concentrate	Finished.................	67.2	22.4	7.1
2	Middling	Re-grind and re-jig........	38.3	15.3	18.4
3	Tailing	Re-grind and table........	7.6	4.3	14.6

Neill jig (Fig. 7) is of the fixed-sieve type. Water currents are produced by a swinging vertical paddle, actuated by a rocker arm. Hutch concentrate only is made and is discharged continuously through three $\frac{3}{8}$-in. spigots from each hutch. The jig was developed for service on gold dredges, to replace undercurrents in the sluice line.

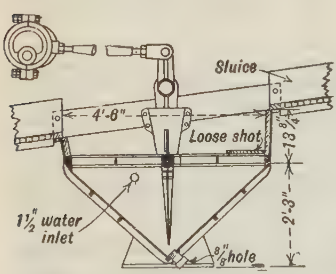

Fig. 7.—Neill jig.

100	7.76	0.07
Through 100	5.20	0.08

On the Natomas No. 7 dredge (*101 J 207*) the jig screens were 2 ft. 5 in. by 3 ft. 8 in., 8-mesh Monel metal, bedded 1 in. deep with BB cast-steel shot. Each jig this size consumed 2.6 hp. at 172 r.p.m. Gold in the jig concentrate all passed 20-mesh and 43 per cent. passed 100-mesh. Jig concentrate contained 6 to 7 per cent. of all the gold caught on the dredge. This was ground in a conical mill and treated in a shaking amalgamator and on plates.

The following data refer to tests on artificial mixtures of cassiterite and stream gravel to determine the suitability of the jig in tin dredging (*106 J 78*). Feed contained 8 lb. tin oxide per cu. yd. Sizing tests of cassiterite and gravel are given in Table 20. Two jigs

were operated in series, the screen area of each about 8 sq. ft.; the sieves were Ton-cap screen with 0.093-in. aperture; bed of ⅛-in. cast-iron shot and gravel, 3.5 to 4 in. deep; 135 to 146 @ 3.5-in. strokes per min.; 50 to 60 gal. per min. hutch water for each jig. The best feed rate was under 4 cu. yd. per hr. Results are given in Table 21. A parallel test

Table 21. Results of Neill-jig tests on tin-gravel

	Test 1	Tests 2–5	Tests 6–11	Test 12
Assay of concentrate, per cent. Sn.	1.67	1.53	0.96	1.12
Ratio of concentration.	15.6	15.1	9.23	9.9
Recovery, per cent.	87.2	86.1	89.5	86.8

in a sluice gave 88 per cent. recovery. In another test on similar material (*112 J 644*) feeding 2 jigs in series, each with 9 sq. ft. screen area, at a rate of 5.8 cu. yd. per hr., the feed containing 0.27 per cent. to 0.53 per cent. cassiterite, the concentrate contained 4.3 to 6.4 per cent. cassiterite and average recovery in the first jig was 85.5 per cent. and in the second, 2.2 per cent. of the total tin in the feed.

bw Brass, woven wire; *sw* Steel, woven wire. Sizing tests of feed given in Table 23,

New Century jig is of the Harz type but usually equipped with a differential motion giving accelerated down stroke to the plunger with corresponding accentuation of pulsion. Suction is decreased by using a rubber flap-valve around the plunger edge that closes on the down stroke and opens wide on the return. Differential motion is produced by raising the plunger against a spring by means of a cam acting against a roller, the plunger being forced down quickly by the spring when the cam releases.

Performance. NEW JERSEY ZINC Co. uses a most elaborate jig equipment in separating willemite and zincite from a calcareous gangue. There are 32 @ 6-compartment jigs with 24 × 36-in. sieves. Data concerning the installation at Franklin Furnace, N. J., are shown in Table 22. One man attends 4 machines. Lost time is given as 10 to 15 per cent., which is exceptionally high, the principal cause being repairs. 5 hp. are consumed per jig. Sizing tests of feeds are given in Table 23. Feed is prepared by dry screening in all cases. At the OGDENSBURG MILL of the same company, treating similar ore, capacity, speed and power consumption are higher than at the Franklin mill. Three men attend 10 machines. Lost time amounts to about 2 per cent., the principal cause being repairs.

Richard's pulsator jig (Fig. 8) consists essentially of a compartmented jigging tank with a fixed screen, underneath which water is fed through a rotating valve. Concentrate is discharged from the screen through the usual gate-and-dam discharge. When operated with closed hutch the bed is subjected to pulsion impulses only and is kept remarkably loose. Speed for such jigging is about 200 r.p.m. Jigging with sized feeds is therefore very rapid and the tonnage per sq. ft. of screen area is many times that of a plunger jig. If suction is desired, the speed is lowered to 150 to 175 r.p.m. and the hutch gate opened. Due to the fact that an 8- to 10-in. bed can be maintained and due also to the relatively light suction, very clean concentrate can be made. Power consumption is much less than for plunger jigs. Water consumption is about the same.

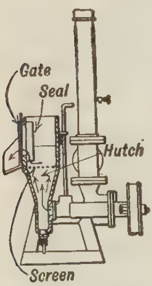

FIG. 8.—Richards pulsator jig.

This jig is most attractive on the basis of laboratory tests but has not worked out well in practice. It does not respond readily to changes in tonnage and richness of feed, probably

on account of the small size of the cells, yet it is limited to small cells to keep down water consumption. It should not be considered for hutch-making service, but is best suited to treatment of closely sized ores with large differences in specific gravity between mineral and gangue, and where low-grade tailing is not essential. In such service it will deliver a high-grade concentrate with small power consumption and not excessive water consumption, and, on account of its small size it can readily be placed high up in the mill where its reject can be spouted by gravity to re-treatment machines. Clean water must be supplied to prevent blinding of screens. At ANACONDA a No. 2 jig treated material sized between 8- and 2.5-mm. in a short test at the rate of 224 tons per 24 r. and made concentrate assaying 9.8 per cent. Cu and tailing about 2.2 per cent. from a feed containing 2.85 per cent. This result compares unfavorably on a metallurgical basis with the work of the Hancock, Harz, Evans and Woodbury jigs at these plants.

At PACIFIC COAST COAL Co., Issaquah, Wash. (*Bul. 28 UW 123*), a laboratory-type Richard's pulsator jig at 110 r.p.m., treating – 3/8 + 3/16-in. raw coal, containing 18.7 per cent. ash made 75.3 per cent. by weight of washed coal containing 13.7 per cent. ash and 24.7 per cent. refuse containing 37.4 per cent.

Shields and Thielmann jig (Fig. 9) is a plunger-type fixed-sieve jig used at the QUINCY MILL for treating unclassified native-copper ore through 5/8-in. grates from steam stamps. The unit is a 4-compartment cast-iron jig tank, 12 in. wide by 24 to 30 in. long, each hutch connected by a 4-in. pipe through the side wall with a vertical cylinder in which runs a piston, eccentrically operated from a common shaft. Eccentrics are individually adjustable and each hutch is fed by a separate water supply. Both gate and hutch discharge are provided.

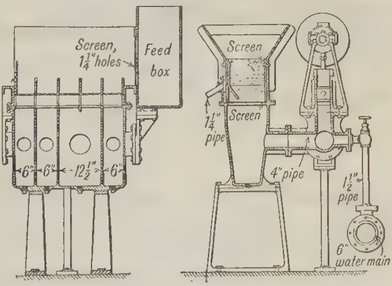

FIG. 9.—Shields and Thielmann jig.

A 4-section installation at the QUINCY mill treats 500 tons per 24 hr. Power consumption is between 3 and 4 hp. for the 16 compartments. The vertical screen between the sections causes size grading in successive discharges. Coarse copper, 3/8-in. to 5/8-in., discharges from gates 1 to 3. Clean concentrate is also taken from hutches 1 and 2. Gates 4 and 5 discharge coarse middling. Gates 6, 7 and 8 are kept closed to accumulate concentrate; gates 9 and 10 discharge middling for re-grinding. The remaining sections discharge middling products of various sizes from 1/8-in. to 40-mesh and of various grades from both gates and hutches. Slime (– 40-mesh) is overflowed from the last compartment.
